## Introduction

ex-intro

DUNE collaborators have prepared this detailed design document which describes the reference design for the DUNE Near Detector Systems (NDS) and serves as an annex to the more abbreviated discussion in the DUNE CDR. The NDS design pulls heavily from both the LBNE near detector design of March 2012, before the LBNE reconfiguration effort eliminated this detector from the project scope, and from the design proposed by Indian collaborators in their DPR of late 2013.

The role of the DUNE Near Detector Systems (NDS) is to minimize the systematic uncertainties of the long-baseline oscillation program and to thus maximize the oscillation-physics potential of the Far Detector. It is important that the Near Detectors improve the sensitivity of the DUNE long-baseline neutrino-oscillation measurements. The enhanced sensitivity they provide will aid in both the analysis of electron-neutrino appearance, the primary oscillation channel, and muon-neutrino disappearance.

The NDS is made up of the following components:

- Fine-Grained Tracker (FGT) near neutrino detector
- Beamline Measurement System
- Near Detector System Data Acquisition system
- External Measurements

The DUNE Fine-Grained Tracker (FGT) near detector consists of a straw-tube tracking detector (STT) and electromagnetic calorimeter (ECAL) inside of a 0.4-T dipole magnet. In addition, Muon Identifiers (MuIDs) are located in the steel of the magnet, as well as upstream and downstream of the STT. The FGT is designed to make precision measurements of the neutrino fluxes, cross sections, signal rates and background rates.

The Beamline Measurement System (BLM) will be located in the region of the Absorber Complex at the downstream end of the decay region to measure the muon fluxes from hadron decay. The

- 2 absorber itself is part of the LBNF Beamline. The BLM is intended to determine the neutrino  
3 fluxes and spectra and to monitor the beam profile on a spill-by-spill basis, and will operate for  
4 the life of the experiment.
- 5 The Near Detector System Data Acquisition system (NDS-DAQ) collects raw data from each NDS  
6 detector's individual DAQ, issues triggers, adds precision timing data from a global positioning  
7 system (GPS), and builds events. The NDS-DAQ is made up of three parts: NDS Master DAQ  
8 (NDS-MDAQ), the Beamline Measurements DAQ (BLM-DAQ) and the Near Neutrino Detector  
9 DAQ (NND-DAQ).
- 10 In addition, external pion production measurements will improve the simulation of neutrino fluxes.

# Chapter 2

## The Near Neutrino Detector: A Fine-Grained Tracker

### 2.1 Introduction

The DUNE Fine-Grained Tracker (FGT) near neutrino detector consists of a straw-tube tracking detector (STT) and electromagnetic calorimeter (ECAL) inside of a 0.4 T dipole magnet. In addition, Muon Identifiers (MuIDs) are located in the steel of the magnet, as well as upstream and downstream of the STT. The FGT is designed to make precision measurements of the neutrino fluxes, cross sections, signal rates and background rates. This document presents the FGT design, which will meet the physics goals and sensitivities of the DUNE experiment.

### 2.2 Motivation

In order for DUNE to achieve the desired neutrino-oscillation sensitivity, the charged-current signal events and neutral-current background events in the DUNE far detector (FD) must be precisely predicted as a function of the parameters and variables that affect oscillations. These include energy, leading lepton (which tags the neutrino flavor) and the momentum and identification of particles generated by neutrino interactions. At the FD, the first and the second oscillation maxima signals occur at about 2.4 GeV and 0.8 GeV, respectively — an energy regime where neutrino cross sections and fluxes have large uncertainties. It is therefore crucial to measure the unoscillated neutrino fluxes and their interactions at the near site.

In addition to the oscillation signal, it is critical to identify and measure processes such as neutral current  $\pi^0$  production, that can mimic oscillation signals at the FD. Thus, the principal focus of the near neutrino detector will be on the neutrino-oscillation energy range of  $E_\nu < 8$  GeV, as well as higher neutrino energies that produce background to the oscillation signal. Furthermore, the  $8 < E_\nu < 20$  GeV energy range can be used as a “control region”, i.e. a region in which to search

for physics beyond the PMNS matrix. Clearly, the measurements must be comparable to those made in the FD, for which the target material is liquid argon (LAr).

Finally, the near neutrino detector must measure nuclear effects, including short-range correlations, two-body currents, pion absorption, initial-state interactions, and final-state interactions. These nuclear effects have an impact on neutrino cross sections and energy determinations, and differences between neutrinos and antineutrinos must be fully understood when searching for CP violation.

The proposed detector will constrain the systematic uncertainties in the DUNE oscillation measurements. Regardless of the process under study, the goal is to have the systematic error less than the corresponding statistical error. The design presented here is the subject of study within the DUNE Science Collaboration. As these studies progress, the design of the DUNE near neutrino detector, referred to as the Fine Grained Tracker (FGT) in this document, may evolve from what is described here.

## 2.3 Overview of FGT Design

A schematic drawing of the FGT design is shown in Figure 2.1. The fine-grained tracker will measure the neutrino event rates and cross sections on argon, water, and other nuclear targets for both  $\nu_e$  and  $\nu_\mu$  charged current (CC) and neutral current (NC) scattering events. The FGT design consists of a straw-tube tracker (STT), consisting of straw tubes, water targets, argon targets, and radiator targets, and an electromagnetic calorimeter (ECAL), both inside a dipole magnet. In addition, muon detectors (MuID) consisting of resistive plate chambers (RPCs) will be embedded in the steel of the magnet.

The FGT has excellent position and angular resolutions due to its low-density ( $\sim 0.1$  g/cm<sup>2</sup>) and high-precision STT. This high resolution is important for determining the neutrino vertex and determining whether the neutrino interaction occurs in the water or argon target. The proposed  $3.5 \times 3.5 \times 6.4$  m<sup>3</sup> STT position inside the dipole magnet with magnetic field  $B = 0.4$  T will enable particle tracking. The nominal active volume of the STT corresponds to 8 tonnes (metric tons, t) of mass, which is mostly due to the STT targets and radiators. Table 2.1 summarizes the performance for the FGT configuration, and Table 2.2 lists the specifications for the FGT.

For a 120-GeV proton beam, the neutrino event rates in the detector will be  $\sim 0.35 \times 10^{-14}$  events/tonne/proton on target. Assuming  $0.5 \times 10^{14}$  protons per beam spill, this corresponds to  $\sim 1.5$  events per spill in the 8-t active volume of the FGT design. Overlaps between interactions are expected to be manageable thanks to the nanosecond-level timing of the FGT relative to the  $\sim 10$ - $\mu$ s beam-spill length.

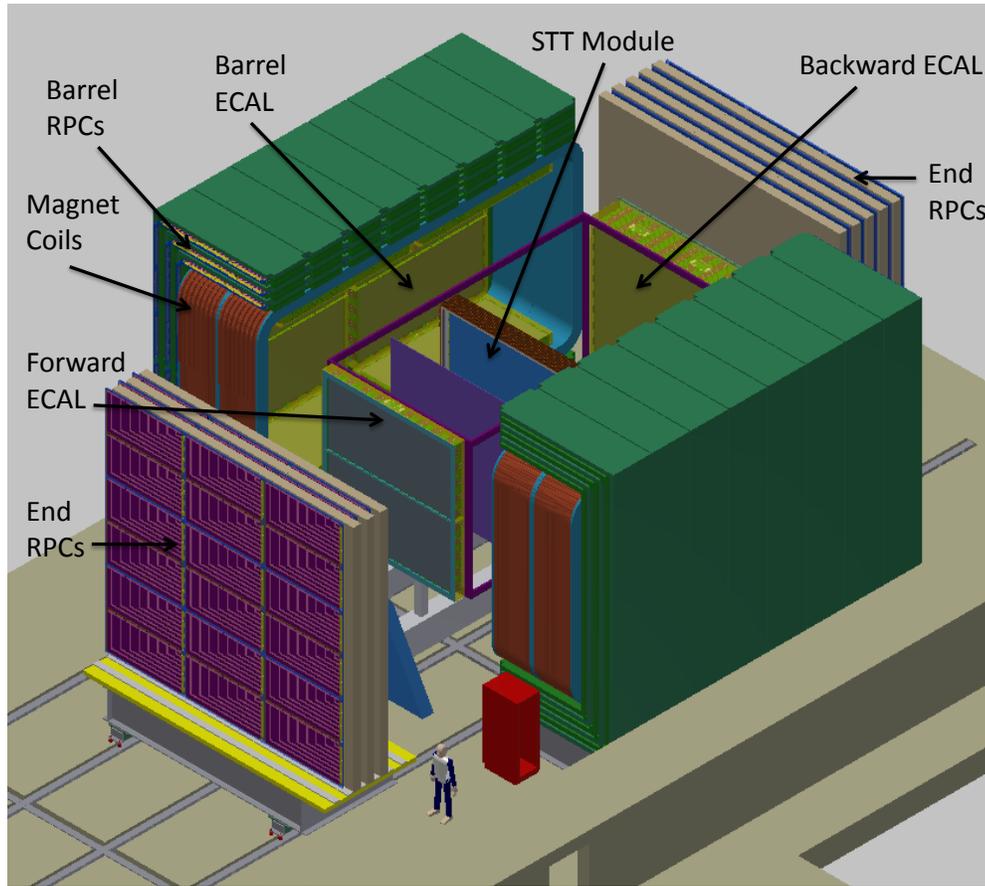

Figure 2.1: A schematic drawing of the fine-grained tracker design.

fig:STT\_

Table 2.1: A summary of the performance for the FGT configuration

Performance Metric	FGT
Straw Tube Detector Volume	3.5m x 3.5m x 6.4m
Straw Tube Detector Mass	8 t
Vertex Resolution	0.1 mm
Angular Resolution	2 mrad
$E_e$ Resolution	5%
$E_\mu$ Resolution	5%
$\nu_\mu/\bar{\nu}_\mu$ ID	Yes
$\nu_e/\bar{\nu}_e$ ID	Yes
NC $\pi^0$ /CCe Rejection	0.1%
NC $\gamma$ /CCe Rejection	0.2%
CC $\mu$ /CCe Rejection	0.01%

comparison

Table 2.2: Specifications for the FGT

Item	Requirement
Inner Magnetic Volume	4.5m × 4.5m × 8.0m
Tracking Detector	3.5m × 3.5m × 6.4m; 80 modules; 107,520 straws
Targets	5.08-cm thick argon, and other nuclear targets
Transition Radiation Radiators	9-mm thick radiators
ECAL	$X_0 = 10$ barrel, 10 backward, & 20 forward; 26,112 scintillator bars
Dipole Magnet	0.4T; 2.4 MW; 60 cm thick steel
Magnetic Field Uniformity	< 2% magnetic field variation over inner volume
MuID	432 RPC modules interspersed between 20-cm thick layers of steel

## 2.4 Straw-Tube Tracking Detector

### 2.4.1 Straw Tubes

The Straw-Tube Tracking Detector (STT) at the center of the FGT is composed of straw tubes with an outer diameter of 1 cm, as well as radiators and targets that reside next to the straw tubes as shown in Figure 2.2.

The straw walls are made by winding together a film of carbon loaded Kapton XC (inner) and a film of aluminum coated Kapton HN (outer), for a total thickness of about  $70 \mu\text{m}$ . The anode wire is gold-plated tungsten with  $20 \mu\text{m}$  diameter. Two consecutive layers of straws are staggered by a half-diameter, glued, and inserted into a carbon-fiber composite mechanical frame to form a single module. One vertical (YY) and one horizontal (XX) module are then assembled together to form a double-module (XXYY) equipped with frontend electronic readout boards. Figure 2.2 shows a schematic drawing of the STT module with four straw-tube planes and radiators. Each XXYY module equipped with radiators is equivalent to  $1.45 \times 10^{-2} X_0$  ( $0.2 \times 10^{-2} X_0$  without radiators), with a radiation length  $X_0 \sim 5.5 \text{ m}$ . The momentum measurement requires that tracks are detected in at least six straw layers. The staggered double layer design, high number of straw planes and double-end readout will contribute to resolving short track disambiguation.

The straw tubes will be filled with a gas mixture of either 70% Ar plus 30%  $\text{CO}_2$  (for modules with nuclear targets) or 70% Xe plus 30%  $\text{CO}_2$  (for modules with radiators). The dimensions of each double module in the reference design will be approximately  $350 \text{ cm} \times 350 \text{ cm} \times 8.0 \text{ cm}$ , including a nuclear target or four radiator planes and four straw planes. For ease of construction and transportation, each double module is made up of two modules, with two straw layers and dimensions of approximately  $350 \text{ cm} \times 175 \text{ cm} \times 4.0 \text{ cm}$ . Each module will have a carbon composite frame around the perimeter for support and will have an attached target or radiator.

13 The modularity of the STT provides for successive measurements using thin nuclear targets (thick-  
 14 ness  $< 0.1X_0$ ), while the excellent angular and spatial resolution allows a clean separation of events  
 15 originating in different target materials.

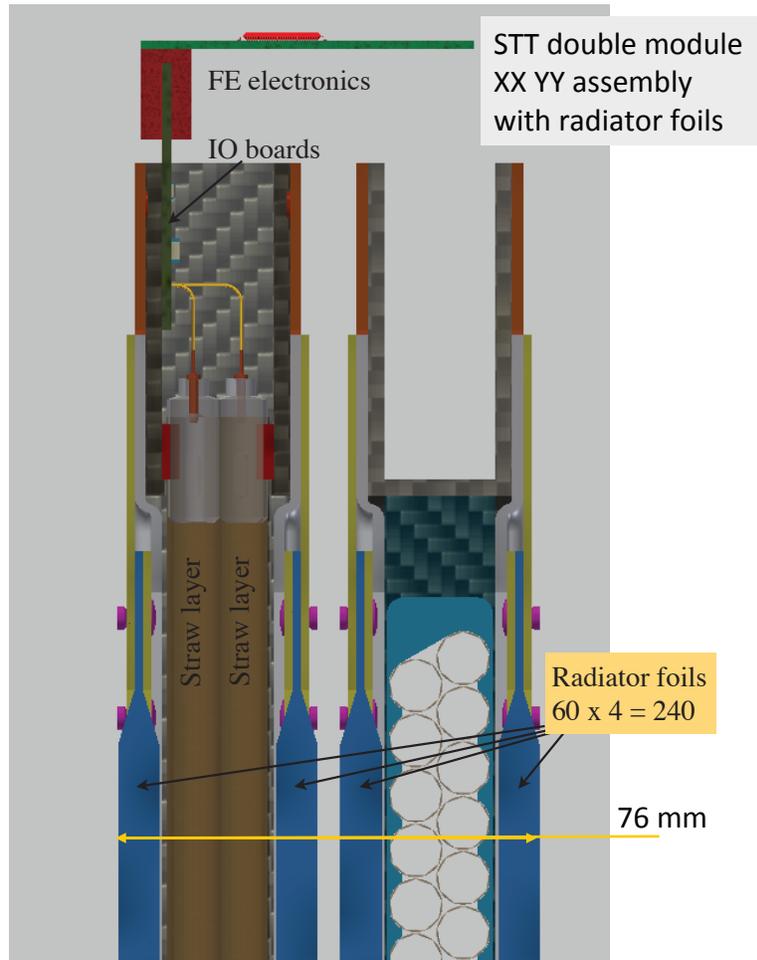

Figure 2.2: A schematic drawing of a STT module with four straw-tube planes and radiators (dark blue shading).

fig:STT\_

16 The STT will have a total of 107,520 straws — corresponding to 336 straws per plane, 1344 straws  
 17 per module — and 80 modules. Both ends of the straw tubes will be read out, leading to a total  
 18 number of electronics channels of 215,040. The total mass of the STT, including targets and  
 19 radiators, is approximately 8 t, corresponding to an average density of  $0.1 \text{ g/cm}^3$ . The thickness  
 20 of the entire 6.4-m-long STT is  $0.3X_0$  without radiators and nuclear targets and  $\sim 1.3X_0$  with all  
 21 radiators and targets included. Specifications for the Straw Tube Detector are shown in Table 2.3.

tab:STT\_detail

22 In addition to tracking charged particles and measuring Transition Radiation (TR), the STT  
 23 provides  $dE/dx$  measurement to identify particles. Figure ?? provides a sample of pions, kaons  
 24 and protons identified via  $dE/dx$  in the STT.

Table 2.3: Straw Tube Detector specifications

Item	Specification
Straw Tube Geometry	1 cm Diameter x 3.5 m Long
Number of Straw Tubes	107,520
Number of Straw Tubes per Plane	336
Number of Straw Tube Planes per Module	4
Number of Straw Tube Sub-Modules per Module	4
Number of Straw Tube Modules	80
Number of Straw Tube Sub-Modules	320
Length of Straw Tube Wire	376.3 km
Number of Electronics Channels	215,040
Number of Modules with Radiators	75
Radiator Thickness per Module	3.6 cm
Radiator Mass per Module	69.1 kg
Number of Modules with Nuclear Targets	10
C Mass per Target Plane	192 kg
Number of Modules with C Target Planes	2
Ca Mass per Target Plane	132 kg
Number of Modules with Ca Target Planes	1
Ar Target Geometry	5.08 cm Diameter × 3.5 m long
Number of Ar Targets per Plane	68
Ar Mass per Target Plane	112 kg
Number of Modules with Ar Target Planes	1
Fe Mass per Target Plane	96.5 kg
Number of Modules with Fe Target Planes	1

fig:Part

## 2.4.2 Radiator Targets

Radiators will be placed in the downstream STT modules and will serve as targets for both neutrino interactions and Transition Radiation (TR) production. Each STT module contains four radiators, where each radiator consists of 60 layers of 25- $\mu\text{m}$  polypropylene ( $\text{C}_3\text{H}_6$ ) $_n$  foils alternating with 60 sheets of 125- $\mu\text{m}$  tulle fabric spacers. The mass of each radiator is  $\sim 27$  kg and the thickness is  $\sim 9$  mm. The use of thin plastic foils regularly spaced allows the emission of transition radiation for electron/positron identification, which is detected by the Xe gas in the straws. The plastic radiators account for about 83% of the mass of each STT module and also provide the main (anti)neutrino target.

## 2.4.3 Nuclear targets

A set of different nuclear targets will be installed in front of the most upstream STT modules, which will not be equipped with radiators. The most important nuclear target is the argon target that matches the DUNE far detector.

This target will consist of planes of cylindrical tubes filled with argon gas pressurized to 140 atm ( $\rho = 0.233$ ), with sufficient Ar mass to provide  $\sim 10$  times the unoscillated statistics expected in a 40 kt far detector. The proof of concept design consisted of 0.5-inch diameter, 3.5-m-long stainless steel tubes, with wall thickness 0.065-inch, as shown in Figure 2.3. In order to minimize the mass of the tube walls, we are investigating the use of a single plane of C-composite tubes with 2-inch diameter and a wall thickness of 0.04-inch.

9 Relevant to argon, a crucial target is calcium which has the same atomic weight ( $A = 40$ ) as argon  
 10 but is isoscalar. Since most nuclear effects depend on the atomic weight  $A$ , inclusive properties  
 11 of (anti)neutrino interactions are expected to be the same for these two targets. This fact will  
 12 allow the use of both targets to model signal and backgrounds in the DUNE far detector (argon  
 13 target), as well as to compare DUNE results for nuclear effects on argon with the extensive data  
 14 on calcium from charged lepton scattering.

15 An equally important nuclear target is carbon (graphite), which is essential in order to get  
 16 (anti)neutrino interactions on free proton, through a statistical subtraction procedure from the  
 17 main polypropylene target ( $C_3H_6$ )<sub>n</sub>. The availability of such a free-proton target will allow accu-  
 18 rate flux determinations and cross section measurements, and, for the first time, a direct model-  
 19 independent measurement of nuclear effects — including both the primary and final-state interac-  
 20 tions — on the argon target relevant for the far detector oscillation analysis. The required carbon  
 21 target mass is about 0.5 t (in addition to the carbon in the STT frames). The corresponding  
 22 expected number of events on H target are  $5.0(1.5) \times 10^6 \pm 13(6.6) \times 10^3 \nu(\bar{\nu})$  CC, where the  
 23 uncertainty is dominated by the subtraction procedure.

24 A stainless steel target in the form of a single thin slab will provide service measurements of  
 25 (anti)neutrino cross-sections for the INO experiment in India.

26 Finally, cylindrical tubes similar to those used for the pressurized Ar gas can be filled with standard  
 27 and heavy water ( $H_2O$  and  $D_2O$ ). The statistical subtraction of  $H_2O$  from  $D_2O$  will result in a  
 28 quasi-free neutron.

29 [Table 2.3](#) gives a reference configuration of the radiators and nuclear targets, listed according to  
 30 their location from downstream to upstream. The final configuration of the nuclear targets will  
 31 require detailed Geant4 simulations of FGT and corresponding physics sensitivity studies.

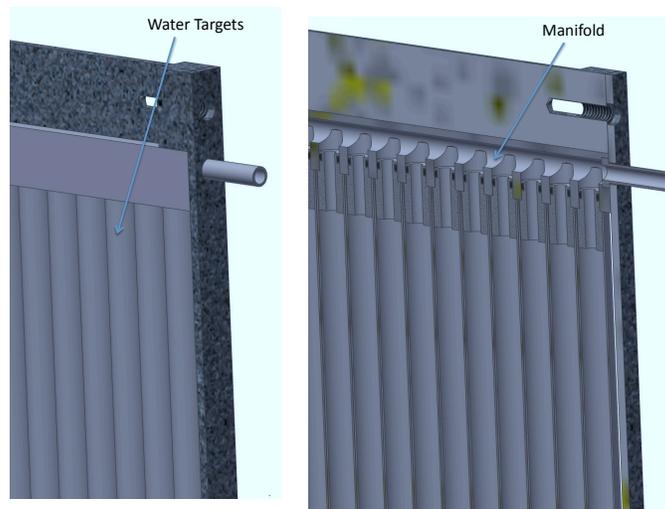

Figure 2.4: Schematic drawing of the water or pressurized-argon targets, made from 0.5-in diameter aluminum tubes.

fig:STT\_

## 2.5 Electromagnetic Calorimeter

32

d-emcalo

33 An electromagnetic calorimeter (ECAL) will surround the tracking volume on all sides and consist  
 34 of three separate pieces: Forward ECAL, Barrel ECAL, and Backward ECAL. The ECAL concep-  
 1 tual design consists of layers of either 1.75-mm-thick (for the forward ECAL) or 3.5-mm-thick (for  
 2 the barrel and backward ECAL) lead sheets and 2.5-cm-wide by 10-mm-thick plastic scintillator  
 3 bars, as shown in Figure 2.4. The scintillator layers for the Forward and Backward ECAL alternate  
 4 as XYXYXY..., while the scintillator layers for the Barrel ECAL are all horizontal along the axis  
 5 of the magnet. The Forward ECAL will consist of 60 layers of scintillator bars, where each bar has  
 6 dimensions  $3.2\text{ m} \times 2.5\text{ cm} \times 1\text{ cm}$ . The Backward ECAL will consist of 16 layers of scintillator  
 7 bars, where each bar has the same dimensions,  $3.2\text{ m} \times 2.5\text{ cm} \times 1\text{ cm}$ . The Barrel ECAL will also  
 8 consist of 16 layers of scintillator bars, where each bar has the same dimensions,  $3.2\text{ m} \times 2.5\text{ cm}$   
 9  $\times 1\text{ cm}$ .

10 The lead sheets and scintillator bars will be assembled and glued together into complete modules  
 11 of dimension  $3.2\text{ m} \times 3.2\text{ cm} \times 81\text{ cm}$  for the Forward ECAL and  $3.2\text{ m} \times 3.2\text{ cm} \times 27.5\text{ cm}$  for  
 12 the Backward ECAL. For the Barrel ECAL, the module dimensions will also be  $3.2\text{ m} \times 3.2\text{ cm}$   
 13  $\times 27.5\text{ cm}$ . Two Barrel modules are placed end-to-end along the sides of the inner surface of  
 14 the magnet (eight Barrel modules total) to provide full coverage of the barrel region. The total  
 15 numbers of scintillator bars in the Forward, Backward, and Barrel ECAL are 7,680, 2,048, and  
 16 16,384, respectively, for a total of 26,112 bars.

17 The scintillator bars will be extruded with holes in the middle of each bar. The holes will then be  
 18 fitted with  $\sim 1\text{-mm}$ -diameter Kuraray wavelength-shifting (WLS) fibers. The fibers will be read  
 19 out by SiPM (silicon photomultiplier) photosensors at each end, making the number of readout  
 1 channels twice the number of scintillator bars for a total of 52,224. The total mass of scintillator  
 2 is 20.9 t, the total mass of Pb is 70.8 t, and the total length of fiber is 83.6 km. Specifications  
 3 for the ECAL are shown in Table 2.4. Figure 2.5 shows a side view of the ECAL (red) inside the  
 4 dipole magnet, where there is very little gap between the Barrel ECAL and the Forward ECAL.

## 2.6 Dipole Magnet

5

d-dipole

6 The STT and ECAL modules will reside inside a 0.4-T dipole magnet for the measurement of  
 7 particle momentum and charge. The magnet will have inner dimensions (inside the coils) 4.5-m  
 8 wide  $\times$  4.5-m high  $\times$  8.0-m long. The magnet has four vertical copper coils, stacked horizontally,  
 9 producing a horizontal magnetic field. The return yoke will be divided into two halves along  
 10 the longitudinal center line to allow the magnet to be opened to service the detector inside, as  
 11 shown in Figure 2.1. Each half yoke will be built from eight “C” (C-shaped) sections, and the  
 12 thickness of the magnet steel will be 60 cm, consisting of  $6 \times 10\text{-cm}$ -thick plates. The magnet  
 13 power requirement with Cu coils is  $\sim 2.4\text{ MW}$ , corresponding to 6 kA at 400 V. The water flow  
 14 required for cooling is 20 l/s. The Dipole Magnet specifications are shown in Table 2.5.

15 The momentum resolution is dominated by multiple scattering in the STT. The momentum reso-

## 3 2.7 Muon Identifier

nd-muid

- 4 The sides and ends of the dipole magnet will be instrumented with a muon identifier detector  
 5 (MuID) that will distinguish muons from hadrons by the ability of muons to penetrate the iron  
 6 without showering or interacting. The MuID will consist of 432 resistive plate chamber (RPC)

modules interspersed between two 10-cm-thick steel plates of the dipole magnet and between 20-cm-thick steel plates at the upstream and downstream ends of the magnet. The MuID is only meant to provide identification of the muon; the muon momentum will be measured by the STT inside the magnetic field. A schematic drawing of the MuID interspersed in the magnet steel is shown in Figure 2.6.

The nominal dimensions of all RPC modules will be  $1\text{ m} \times 2\text{ m}$  with active areas of  $96\text{ cm} \times 196\text{ cm}$ . Each module has 256 X strips at 7.65-mm pitch and 128 Y strips at 7.5-mm pitch. The modules will be grouped into trays, each containing six modules, and the trays will be sufficiently wide to allow overlapping modules. The end RPC trays have dimensions of  $2\text{ m} \times 6\text{ m}$ , and there are three trays per plane. The downstream end has five planes, corresponding to 15 trays and 90 RPC modules. The upstream end has three planes, corresponding to nine trays and 54 RPC modules. The vertical barrel-RPC trays have dimensions of  $2.5\text{ m} \times 4\text{ m}$ ,  $2.8\text{ m} \times 4\text{ m}$ , and  $3.1\text{ m} \times 4\text{ m}$  for the inner, middle, and, outer planes, respectively, corresponding to 24 trays and 144 RPC modules. The horizontal barrel-RPC trays have dimensions of  $2.2\text{ m} \times 4\text{ m}$ ,  $2.5\text{ m} \times 4\text{ m}$ , and  $2.8\text{ m} \times 4\text{ m}$  for the inner, middle and outer planes, respectively, corresponding to 24 trays and 144 RPC modules. Overall, there are a total of 72 trays, 432 RPC modules, and 165,888 strips and electronic channels.

The downstream MuID will contain five steel planes of overall dimensions  $6 \times 6 \times 0.2\text{ m}^3$  (283.5 t) and five RPC planes, while the upstream MuID will contain three steel planes ( $170.1\text{ t}$ ) of dimensions  $6 \times 6 \times 0.2\text{ m}^3$  and three RPC planes. The barrel MuID will contain 24 planes (three layers  $\times$  eight sides) of RPCs. The RPCs will have a total thickness of 15 mm and a gap width of 2 mm. One possible gas mixture could be of Ar (75%), tetrafluoroethane (20%), isobutane (4%), and sulphurhexafluoride (1%). Figure 2.7 shows a schematic drawing of an end RPC tray, while Figure 2.8 shows a schematic drawing of an RPC module. MuID specifications are shown in Table 2.6.

## 2.8 FGT Instrumentation

The instrumentation includes both fast readout electronics for the subdetectors and the slow control ( $\mathcal{O}$  seconds) of the subdetectors, involving monitoring the humidity, temperature, gas pressure, etc. There is considerable synergy in the information gathered in the STT, ECAL and MuID. Both the STT and ECAL are required to measure the total charge and the time associated with a given hit. The MuID RPCs are required to provide the position and time associated with a traversing track. Similarly, the slow control of the subdetectors share many features. A brief description of the subdetector instrumentation is presented here, while Table 2.7 summarizes the number of electronics channels for each of the subdetectors.

Table 2.7: The number of electronics channels for each of the three detector systems

Detector	Number of Electronics Channels
STT	215,040
ECAL	52,224
MuID	165,888

### 2.8.1 Readout Electronics

The electronics for the three subsystems, STT, MuID, and ECAL, are all “fast” systems, i.e., all of the signals are in the few-to-10 nanosecond range. The STT output has a roughly 10-nanosecond rise time with a total integrated charge of about 100 electrons per centimeter. The gain of the STT drift tubes are typically  $10^4$  to  $10^6$ , so over a collection time interval of  $\sim 100$  ns the integrated charge is  $10^6$  to  $10^8$  electrons. The MuID system contains RPCs that can operate in either streamer mode or avalanche mode; the difference being that streamer mode is not proportional to the deposited charge, whereas the avalanche mode is. The rise time of the RPC signal is a few nanoseconds and charge is collected immediately; the collected charge can be large, up to 100 pC. The ECAL signals come from a SiPM that converts the light from the scintillator strips to an electronic signal. The deposited charge in the scintillator will give rise to  $10^3$  to  $10^5$  photoelectrons. The gain of a SiPM is  $\sim 10^6$  and has a rise time of a few nanoseconds, so the total charge can be  $> 100$  pC. As these three systems all have gain and are fast, it is hoped that a common electronics system may be possible.

The requirements for each system are very similar: a fast output and both an ADC and a TDC on each channel. Additionally, for the STT straw tubes it is desirable to wave-form digitize the analog signal in order to enhance the ability to separate the ionization signal from the transition radiation signal. The total channel count is 433,152 channels; this is broken out into 215,000 for the STT, 165,000 for the MuID, and 52,224 for the ECAL. Most available electronic systems from existing experiments don’t quite meet these requirements or are too expensive to implement for this channel count (\$50/channel has been allocated). Recently, an interesting new ASIC development for an upgrade to the ATLAS muon system at the LHC has come out of BNL (see talk given by Gianluigi De Geronimo at the ACES 2014 meeting at CERN in March 2014). A schematic of the newly developed chip (VMM2) is shown in Figure 2.9. It handles 64 channels and produces both

23 fast ADC and TDC outputs. It has been fabricated and tested and should be ready by 2017, long  
24 before it will be needed for DUNE. The VMM2 features are the following:

- 25 • front-end electronics (ASIC)
- 26 • more than 2.3 million channels total
- 27 • operation with both charge polarities
- 28 • sensing element capacitance of 10-200 pF
- 29 • charge measurement up to 2 pC at  $< 1$  fC RMS
- 30 • time measurement  $\sim 100$  ns at  $< 1$  ns RMS
- 31 • trigger primitives, neighbor logic
- 32 • low power, programmable

33 The VMM2 chip will be explored as the first option for the NND readout.

## 34 **2.8.2 Humidity and Temperature Monitoring**

35 Humidity is detrimental to all the FGT subdetectors. To maintain a low level of humidity and  
1 to maintain a desired temperature, both STT and ECAL subdetectors will have dry nitrogen  
2 circulating within their outer layers. A similar arrangement might be made for the RPCs, as  
3 well. Regarding the magnets, magnet coils are cooled by water, while the magnet yokes are  
4 instrumented with RPCs that must remain dry. Thus, a continuous control of humidity in all  
5 these detectors is needed. Just as for humidity, temperature must be continuously monitored in  
6 all of the subdetectors in order for the electronics to not overheat.

## 7 **2.8.3 Gas Leak Monitoring in the STT and MuID**

1 Gas leaks need to be monitored in the STT and MuID. The STT will employ Xe gas, which helps  
2 with the measurement of transition radiation. Xe gas is expensive and, hence, will be recirculated;  
3 leak-monitoring is particularly important here. The requirement on leaks is less stringent for the  
4 RPCs, which have less expensive gas.

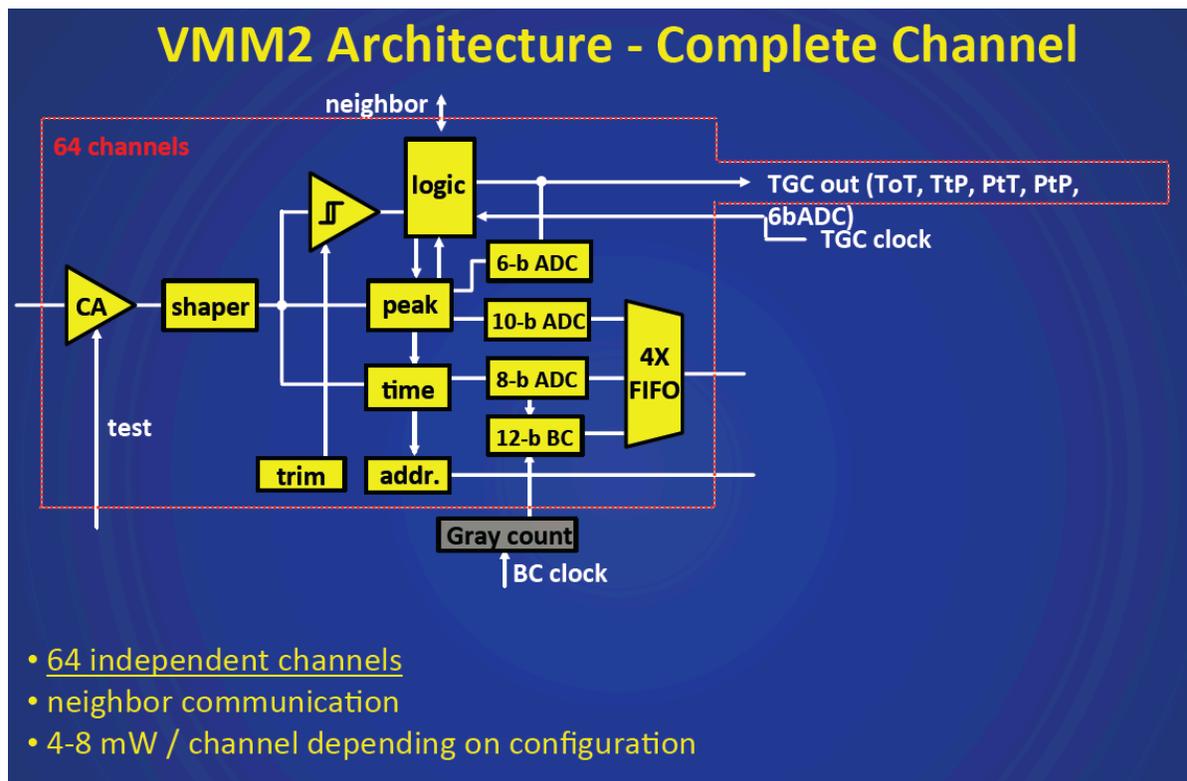

Figure 2.10: A schematic drawing of the VMM2 circuit.

fig:VMM2

## 5 **2.8.4 Magnet Monitoring**

6 The water flow (pressure gradient) will be continuously monitored in order to ensure that the  
7 magnet does not overheat. Also, all power sources instrumenting the FGT and its readout need  
8 to be monitored for appropriate voltage and current.

## Chapter 3

# Near Detector Beamline Measurements

### 3.1 Introduction

This chapter outlines the DUNE strategy for measurements of secondary beam particles in the region behind the beam absorber. Those measurements are designed to provide constraints on the neutrino flux at the near and far detectors, and data on the pulse-to-pulse variation of the beam for beam diagnostic purposes. A description of equipment for monitoring the proton beam's interaction with the proton target can be found in Volume 2: The Beamline at the Near Site.

The measurements and apparatus described in this chapter fall into the category of equipment designed specifically for DUNE to detect muons exiting the decay tunnel.

### 3.2 Design Considerations

#### 3.2.1 General

The requirements for the beamline measurements, as discussed in the NDC requirements documentation [1],

old LBNE reference

are intimately related to how well the neutrino flux must be known. Given that DUNE does not have the luxury to construct identical Near and Far Detectors, a near-far comparison is more complicated than it was in the MINOS experiment [2], for example. While external hadron-production measurements can place strong constraints on the pion and kaon production in the target, they do not provide any confirmation of the simulation of other key features, such as the horn focusing, secondary interactions, and the pion scattering and absorption in the air-filled decay

15 volume.

16 In addition to the external measurements, covered in Section [??](#), [ch:ext-meas](#) that confirm the simulation of  
 17 the thick target, horn material, decay tunnel and absorber, it is desirable to constrain the flux by  
 18 making independent measurements at the 4–5% level of the muons that penetrate the absorber.  
 19 It would not be practical to do this for all penetrating muons, but sufficient measurements at a  
 20 few positions can be done in a cost-effective way.

## 21 3.2.2 Muon Measurements [ion-meas](#)

2 The dominant, two-body decays of pions and kaons that produce neutrinos also result in the cre-  
 2 ation of daughter muons. Monitoring the muons exiting the decay volume can provide information  
 3 about the direction, size, shape and flux of the neutrino beam. The daughter muon and neutrino  
 4 energies in those two-body decays are completely anti-correlated. For example, a  $\pi^+ \rightarrow \mu^+ \nu_\mu$   
 5 decay will result in a  $\nu_\mu$  with an energy,  $E_\nu$ , between zero and  $0.43E_\pi$  plus a  $\mu^+$  with an energy of  
 6  $E_\mu = E_\pi - E_\nu$  between  $0.57E_\pi$  and  $E_\pi$ . This has the effect that the muon takes 79% of the pion  
 7 energy on average, leaving the neutrino with only 21%. Thus, on average, the muon energy is 3.75  
 8 times that of the neutrino.

9 The primary physics goal of DUNE is to measure the transmutation of  $\nu_\mu$ s to  $\nu_e$ s over the 1300km  
 10 between Fermilab and the far detector site. Therefore it is essential for DUNE to cross-check the  
 11 estimate of background  $\nu_e$ s present in the beam by using several methods to measure their rates  
 12 at the Fermilab site. There are two dominant sources of  $\nu_e$ s present in the neutrino beam, muon  
 13 decays and kaon decays. The muon systems are designed to directly measure the muons that  
 14 penetrate absorber with an energy threshold as low as possible, i.e. directly measure those muons  
 15 whose decays are a major source of background  $\nu_e$ s, . A measurement of the spectrum of those  
 16 muons will translate directly into constraints on the spectrum of background  $\nu_e$ s. That constraint  
 17 has the enormous advantage of being independent of poorly understood neutrino-nucleus cross  
 18 sections.

19 Because muons and neutrinos come from the same parent pion and kaon decays, a measurement  
 20 of the absolute muon flux in conjunction with the energy spectrum seen in the muon monitors  
 21 can constrain the absolute neutrino flux. The goal for the DUNE muon monitors is to determine  
 22 the absolute muon flux to an accuracy of 5% above a muon energy of 6 GeV (which corresponds  
 23 to a neutrino energy of 1.6 GeV) in the central part of the absorber. [fig:nu\\_mumon\\_trac](#) Figure 3.1 shows the total  
 24 simulated neutrino flux at the Far Detector overlaid with the flux from only neutrinos having pion  
 25 or kaon parents that contribute to the signal seen in the muon monitor. The simulation shows  
 26 that between 3 GeV and 10 GeV, more than 90% of the neutrinos in the Far Detector come from  
 27 this subset.

28 It is essential to monitor the stability of the beam direction over time. [fig:fluxRatio](#) Figure 3.2 shows the effect  
 29 on the muon-neutrino flux in the Far Detectors when the beam is misaligned by 0.4 mrad. For  
 30 example, above 6 GeV, the ratio of the Far Detector flux over the Near Detector flux changes by  
 31 2%. To keep the change in the neutrino beam less than 1% in all energy bins, the beam direction  
 32 must be known to a precision of approximately 0.2 mrad. Because the muon monitors will be

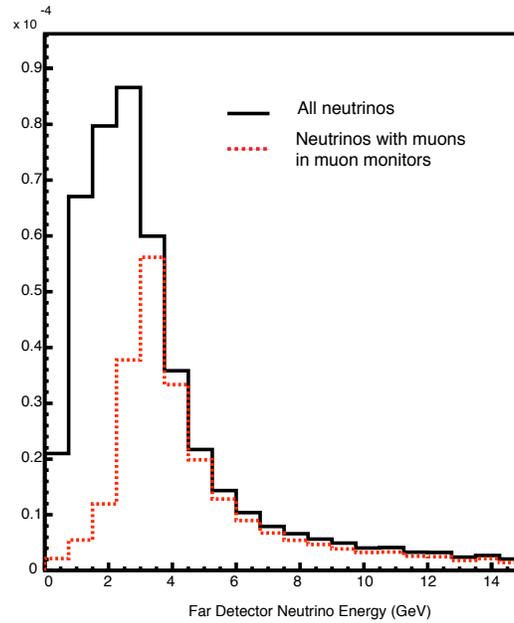

Figure 3.1: The total simulated neutrino flux at the Far Detector (black solid) overlaid with the neutrino flux, also at the Far Detector, coming from neutrinos with pion or kaon parents that contribute to the muon-monitor signal (red dashed), averaged over the back of the absorber. As shown in Figure 3.6, the muon systems will probe down to 1.5 GeV in neutrino energy on the beam axis.

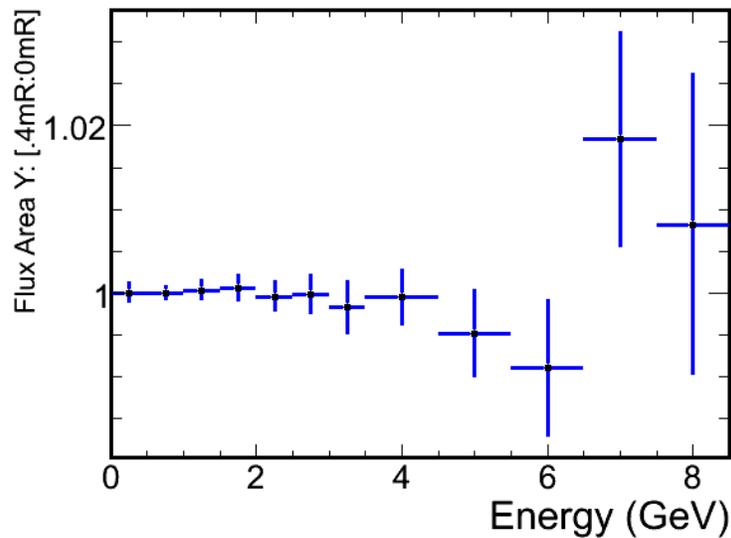

Figure 3.2: Ratio of the neutrino flux on-axis to the flux 0.4 mrad off-axis at the Far Detector position.

33 located approximately 275 m from the beam target, this requires a measurement of the muons to  
34 an accuracy of approximately 5 cm.

35 The rate of muons crossing the monitors will be quite high, with preliminary LBNF beam simula-  
36 tions suggesting approximately 50 million muons per  $\text{cm}^2$  for a pulse of  $10^{14}$  protons-on-target. The  
1 muon monitors must also be capable of operating in a high-radiation environment. For example,  
2 the expected dose in the area downstream of the NuMI absorber is as high as 100 MRad per year  
3 [\[3\]](#). ref:NuMIBeamMonitors

### 4 3.3 Muon-Measurement Facilities

5 The muon measurements are carried out in the region immediately following the hadron absorber  
6 at the end of the decay tunnel, below the Absorber Service Building (LBNF 30). A view of the  
7 absorber area and the muon alcove is shown in Figure 3.3. fig:AbsorberPerspectiveOverview The axis of the decay pipe cuts across  
8 the muon alcove at an angle, and the size of the alcove is largely determined by the requirement  
9 that it contain the shadow of the four-meter-diameter decay pipe, projected through the alcove,  
10 as shown in the elevation view of Figure 3.5. fig:AbsorberElevationView

11 fig:AbsorberPerspectiveOverview2 Figure 3.4 shows the downstream side of the absorber and a conceptual layout of the muon systems  
12 described in various sections of this chapter. The absorber itself is encased in concrete. The first set  
13 of muon-measurement devices, from left to right, is a set of three variable-pressure gas Cherenkov  
14 counters, which are mounted directly to the rear wall of the absorber. Following that is an array  
1 of diamond ionization detectors and finally a set of stopped-muon counters which are interspersed  
2 between walls of steel “blue blocks”. The blue blocks are there to provide several depths at which  
3 to monitor the stopped muons as they range out in the material. A second array of ionization  
4 devices will also be placed farther downstream within the blue blocks.

5 fig:AbsorberPerspectiveOverview2 A perspective view of LBNF 30 is shown in Figure 3.4, and a detail of the lower level of Absorber  
6 Hall is given in Figure 3.5. fig:AbsorberElevationView The HV, water systems and gas systems for the muon monitors will  
7 be located nearby on the lower level. The readout electronics will be located in racks close to the  
8 surface.

9 It is important to have precise knowledge of the amount of material muons pass through before  
10 they are registered in the muon systems. The absorber itself is a complex, heterogeneous assembly  
11 of various materials. fig:AbsorberElevationView Figure 3.5 show the absorber conceptual design (more detail is available in  
12 Volume 2 of this CDR). A hole in the front side of the absorber, at left, is both surrounded and  
13 followed by the aluminum core of the absorber. The core is then surrounded by steel and standard  
14 steel “blue blocks”, which are in turn surrounded by concrete. This complex geometry must be  
15 carefully understood and simulated in order to make the muon measurements effective.

16 fig:AbsorberThickness Figure 3.6 shows the energy lost by a horizontal muon as it traverses the absorber, as a function  
17 of the distance from the beam axis along a  $45^\circ$  line perpendicular to the beam axis. In the central  
1 region, roughly to a distance of 105 cm, the muons lose between 5.0 to 6.4 GeV, so that the  
2 lowest-energy muons leaving the absorber at that point correspond to neutrino energies of  $\sim 1.5$

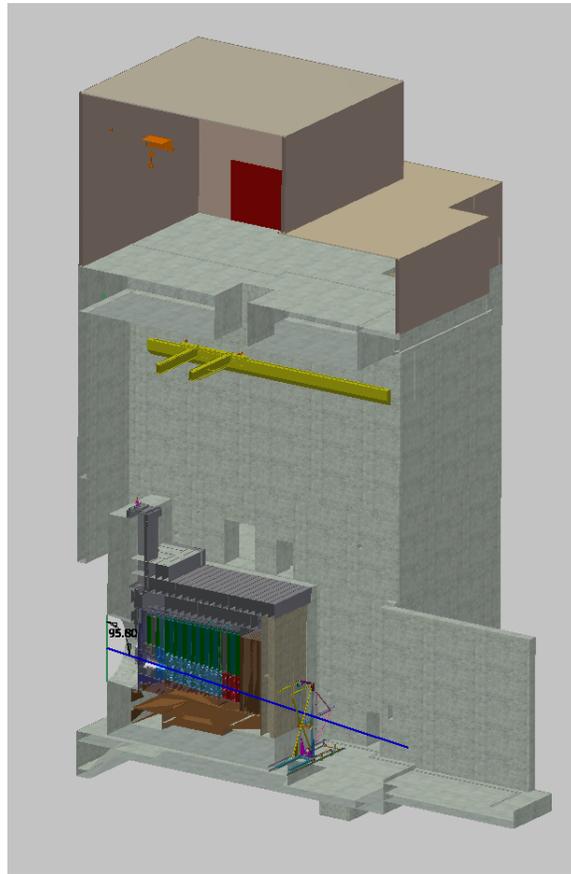

Figure 3.3: The Absorber Hall overview. The Absorber Service Building (LBNF 30) is on the surface and allows for crane access to the Absorber Hall. The muon alcove is directly behind the absorber.

fig:Absorber

Figure 3.4: A perspective view of the Absorber Hall area.

fig:Absorber

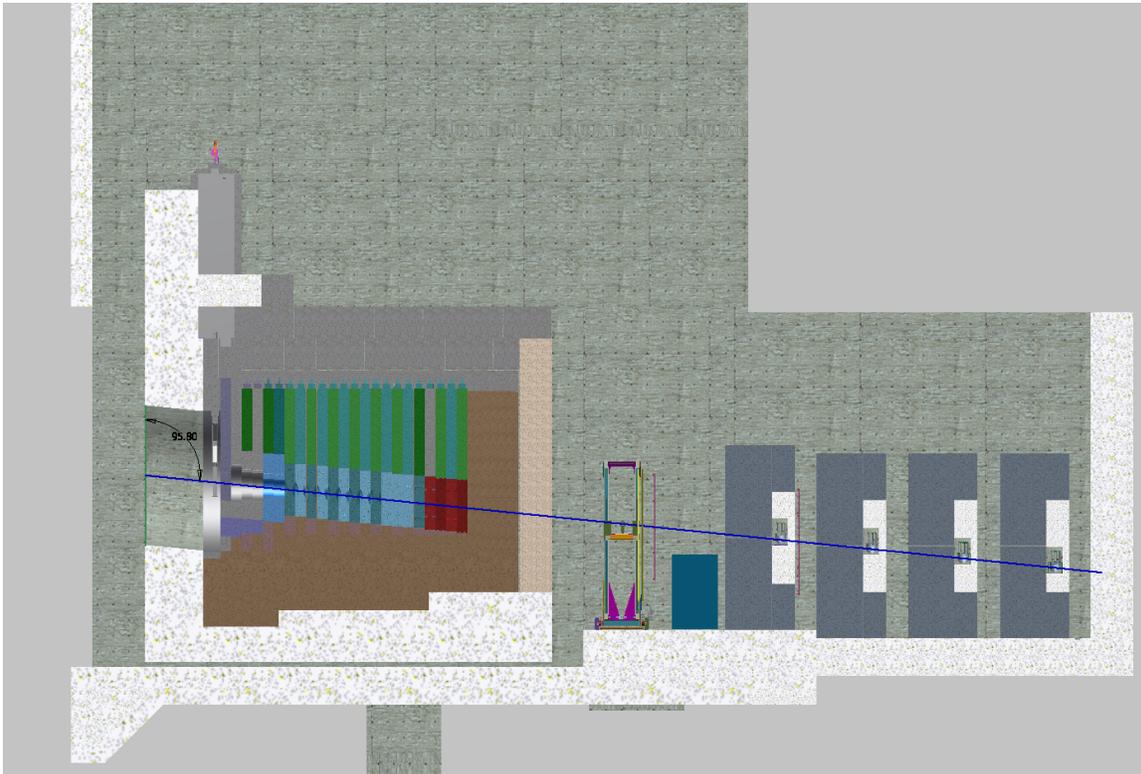

Figure 3.5: Absorber conceptual design. The figure shows the elevation view of the absorber at the end of the decay tunnel. The beam axis is shown by the blue line. The absorber is constructed of several different materials as shown: aluminum core in blue and grey, concrete (grey and tan), and steel (in brown and green).

fig:Absc

3 to 2.0 GeV. At a radius of roughly 105 cm, the full thickness of steel causes the muons 10 GeV or  
 4 more, corresponding to neutrino energies of  $\sim 2.6$  GeV. From the perspective of the muon systems  
 5 it will be desirable to lower these thresholds if possible. This might be accomplished by using more  
 6 aluminum in the front part of the absorber or by judiciously locating detectors inside the absorber  
 7 material.

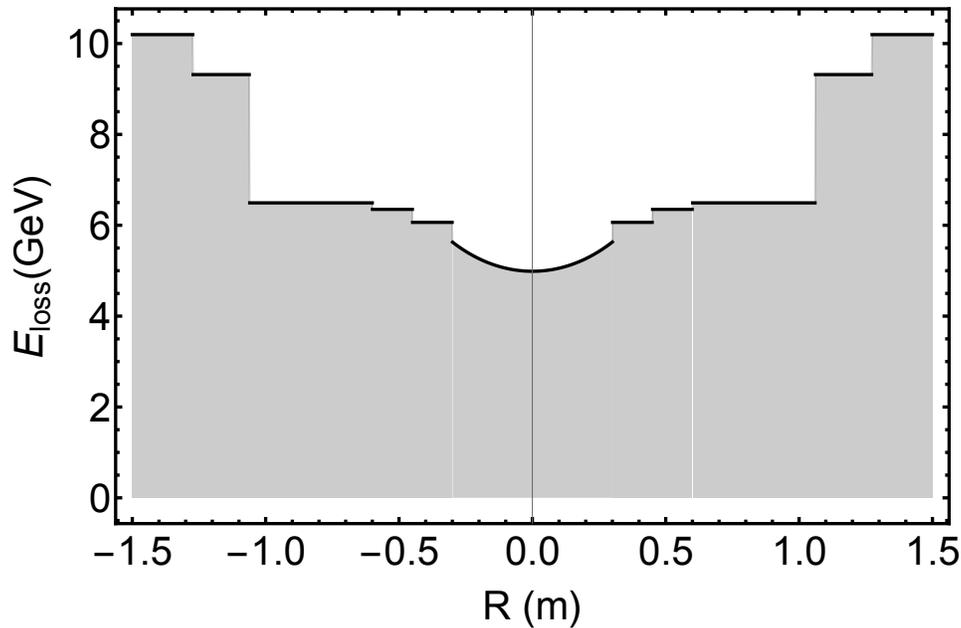

Figure 3.6: The energy loss a muon, parallel to the beam axis, experiences as it traverses the material in the absorber. The muon's energy loss is plotted versus the distance from the beam axis, along a  $45^\circ$  line perpendicular to the beam axis. Muons suffer between 4.7 and 9.3 GeV of energy loss depending upon where they cross the absorber.

fig:Absc

## 8 3.4 Muon Cherenkov Detectors

Cherenkov

### 9 3.4.1 Introduction

10 A Cherenkov variable-pressure, gas Cherenkov counter, operated in differential mode will be de-  
 11 ployed downstream of the absorber. The counter will be mounted on a movable stand that will  
 12 allow the system to scan in a plane transverse to the beam axis. The Cherenkov counter deployed  
 13 by DUNE will not image individual Cherenkov rings, but rather will see the integrated signal from  
 14 many muons due to the very large instantaneous flux. In addition, by varying the radiator gas  
 15 pressure, and hence the Cherenkov threshold, the system's index of refraction will vary, allowing  
 16 it to map out the muon momentum distribution.

17 Figure 3.7 shows the expected distribution of velocities,  $\beta$  ( $v/c$ ), for muons and electrons after  
 18 exiting the absorber. Figure 3.8 shows the expected angle with respect to the beam for electrons  
 19 and muons with similar velocities (implying that both are visible above the same Cherenkov

fig:MuonBeta

fig:MuonAngle

10 threshold). Despite the similar velocities, the muons are much more likely than the electrons to  
 11 be directed parallel to the beam.

1 Therefore, a detector that takes advantage of the directional nature of Cherenkov light will have  
 2 less background contributions from electrons and other isotropic background particles such as  
 3 neutrons, than will an ionization system, for example.

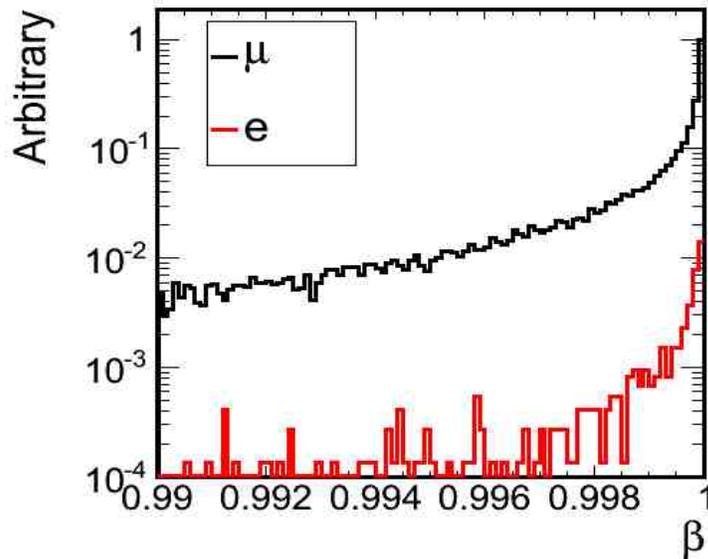

Figure 3.7: Simulated electron and muon velocities exiting the absorber. This plot is based on a simulation `gnumi[4]` of the LBNF beamline.

fig:Muon

### 4 3.4.2 Reference Design

5 The simple Cherenkov counter design employs a gas radiator contained in a pressurized tube. The  
 6 very forward Cherenkov light in a narrow cone of  $\pm 1$  mrad is collected at the end of the tube  
 7 by a mirror that reflects the light 90 degrees towards a photosensor located outside the high-  
 8 radiation field of the muon beam. The gas pressure, varied from vacuum to twenty atmospheres,  
 9 will determine the index of refraction, and hence the Cherenkov angle versus muon-momentum.  
 10 Several such tubes will be constructed in an array transverse to the beam direction. The resulting  
 11 pressure scan will give the momentum distribution of the muons at an array of points across the  
 12 end of the absorber.

1 [fig:CherenkovCounterDetail](#)  
 2 Figure 3.9 shows how the Cherenkov system will be constructed. Safety considerations suggest  
 3 that the diameter of the radiator tube and light-guide tube be six inches or less. A photosensor,  
 4 located outside the direct radiation field of the muons, will view the primary mirror through a  
 5 telescopic optical system.

5 The preferred option is to use a gas Cherenkov system containing a noble gas with a high index  
 6 of refraction, where the density of the gas can be varied to change the Cherenkov threshold. The  
 7 noble gas will reduce potential degradation due to reactivity in the high radiation field of the post-

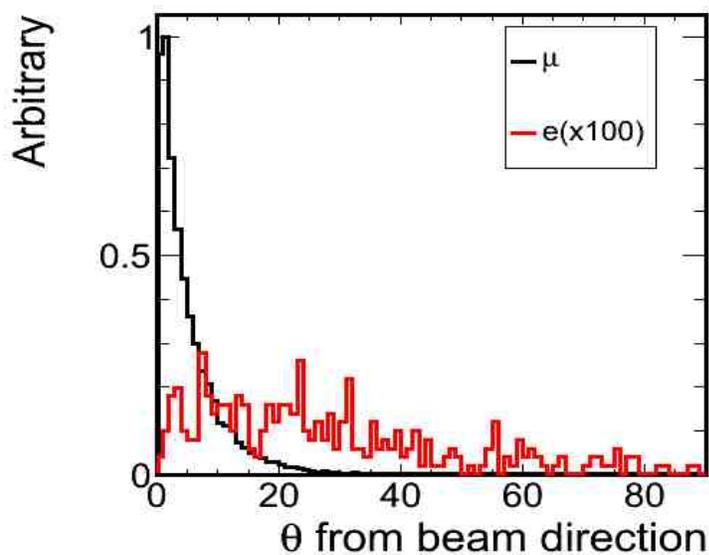

Figure 3.8: Simulated plot of angle with respect to the beam for electrons and muons exiting the absorber. This plot is based on a gnumi simulation of the LBNF beamline.

fig:Muon

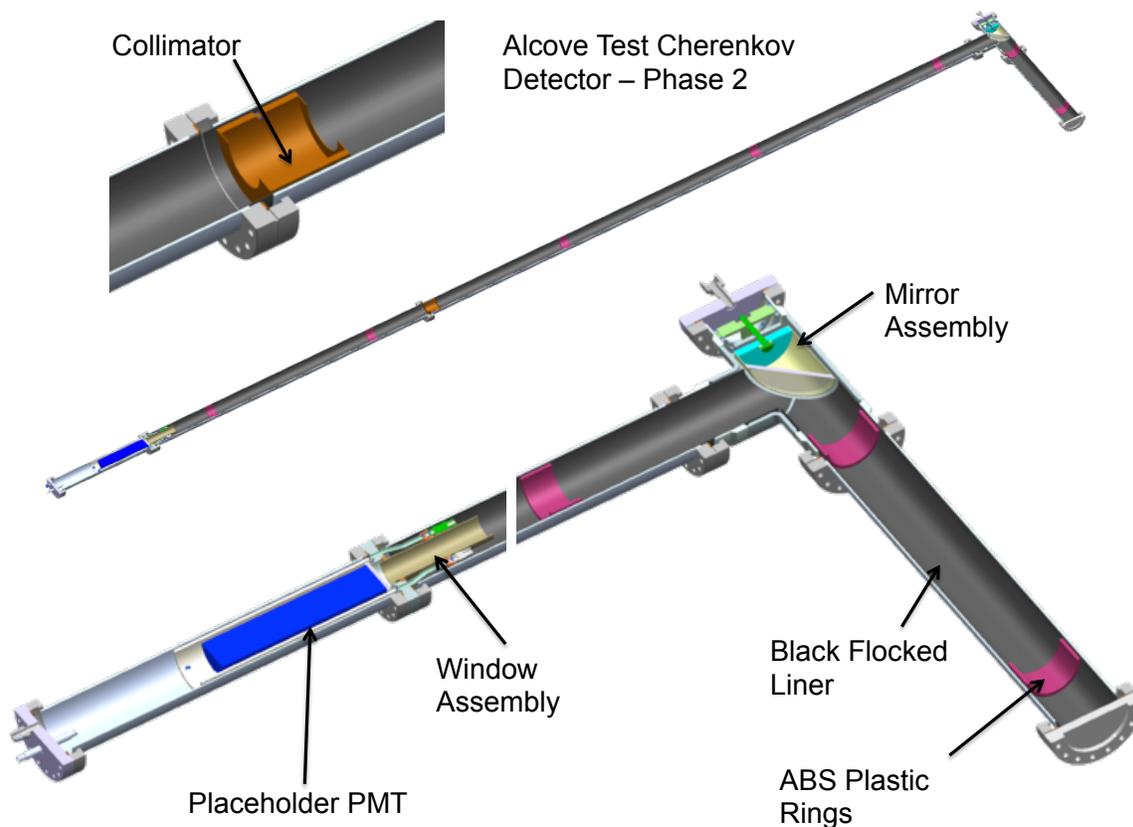

Figure 3.9: The Cherenkov counter prototype design. Muons at threshold momentum emit forward Cherenkov light which is reflected via one flat mirror (45 degrees) to a PMT located outside of the muon radiation field.

fig:Cher

8 absorber environment. Varying the pressure will provide more information about the momentum  
9 spectrum of the muons.

10 The combination of a flat mirror and a  $90^\circ$  mirror will reflect light out to a PMT. The UV-sensitive  
11 PMT will collect light from normal incidence on the primary mirror with a 2 mrad acceptance, the  
12 light yield per particle will be approximately one photon near threshold. That is more than ample  
13 light for the system where the particle flux is of order  $10^7$  per  $\text{cm}^2$  through the radiator section.

### 14 3.4.3 Prototype Development and Testing

15 A prototype Cherenkov counter, along with associated fully automated gas systems, HV systems,  
16 and data acquisition system has been constructed and is undergoing testing in the NuMI neutrino  
17 beam's muon alcove 2. In addition, three diamond detectors [5] for ionization measurements have  
1 also been installed into the alcove. Figure 3.10 shows the prototype detectors in NuMI alcove 2.

2 The counter has an automated gas system with a settable pressure that ranges from vacuum to 20  
3 atm, corresponding to muon Cherenkov thresholds of 200 GeV/c and 1 GeV/c respectively. When  
4 operated at vacuum, the PMT registers all background light unrelated to the gas, e.g. transition  
5 radiation, light from particles hitting the window and PMT glass. Those contributions are observed  
6 to be very small relative to the coherent, directional Cherenkov light.

7 The counter is constructed with a 1 meter long radiator section as shown in Figure 3.9. A 20 foot  
8 extension allows the reflected Cherenkov light to travel to a sapphire pressure window viewed by  
9 a photo multiplier tube.

10 The prototype is now fully integrated into NuMI operations and real-time waveforms can be viewed  
11 online as shown in Figure 3.11. The top panel shows the waveform from the Cherenkov counter  
12 at 2 atm gas pressure, that corresponds to a muon momentum threshold of 3 GeV/c. The second  
13 panel shows the waveform from a  $9\text{mm} \times 9\text{mm}$  diamond detector mounted to the front flange of  
14 the Cherenkov radiator section as shown in the inset of Figure 3.10.

15 The extracted NuMI proton beam, Resistive Wall Monitor (RWM) signal is also recorded with an  
16 identical digitizer. That allows a direct, bucket-by-bucket (individual proton pulses) comparison  
17 of the proton current onto the NuMI primary proton target, and the muons measured after the  
18 absorber with a 400ps time resolution.

19 A second set of muon detectors, the final DUNE design, are being constructed at this time (2015).  
1 They are being installed directly behind the NuMI proton beam dump (muon alcove 1). They will  
2 be mounted on a movable stand, and the entire setup will be eventually transferred the DUNE  
3 absorber hall. The higher radiation environment of alcove 1 will be more similar to the eventual  
4 DUNE installation. It will allow the DUNE muon detectors to be calibrated in the NuMI beam  
5 and ready for use in the DUNE beam.

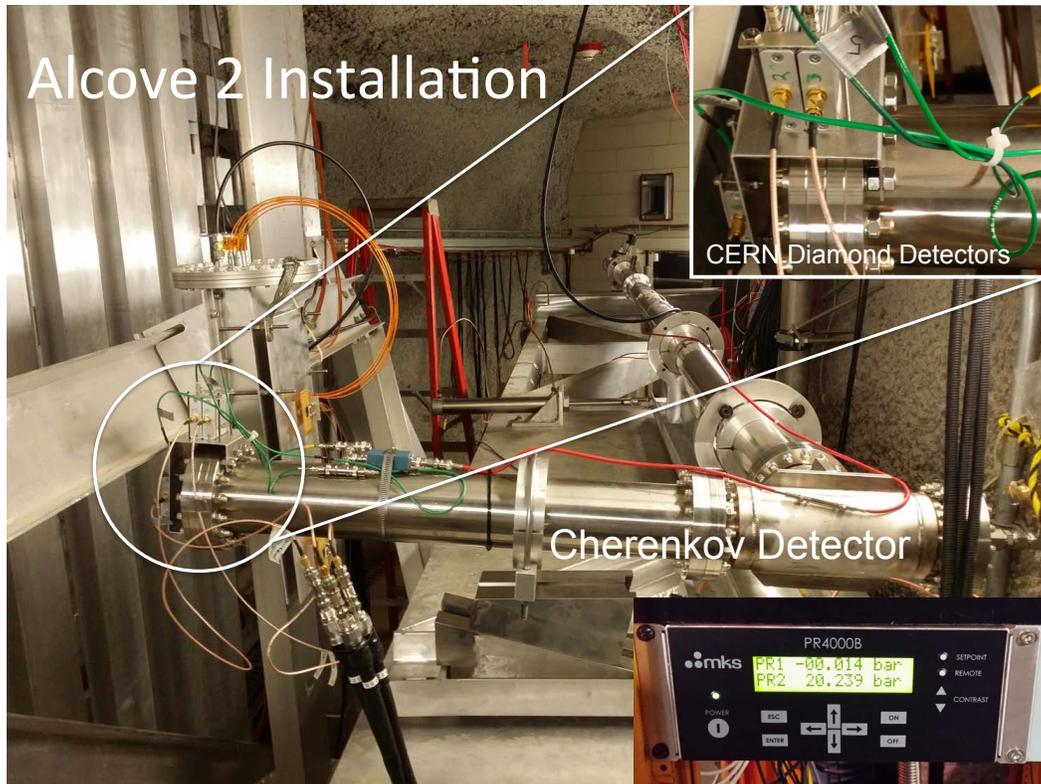

Figure 3.10: A prototype muon gas Cherenkov detector for DUNE. Muons travel through an L-shaped 4" Conflat pipe filled with a pressurized gas. A flat mirror mirrors directs the optical photons to a photo multiplier. The lower right inset shows the 20 bar MKS pressure reading achieved by the Cherenkov gas system, and the inset on the upper right shows the CERN/Cividec diamond detectors mounted to the Cherenkov housing.

fig:Alcove

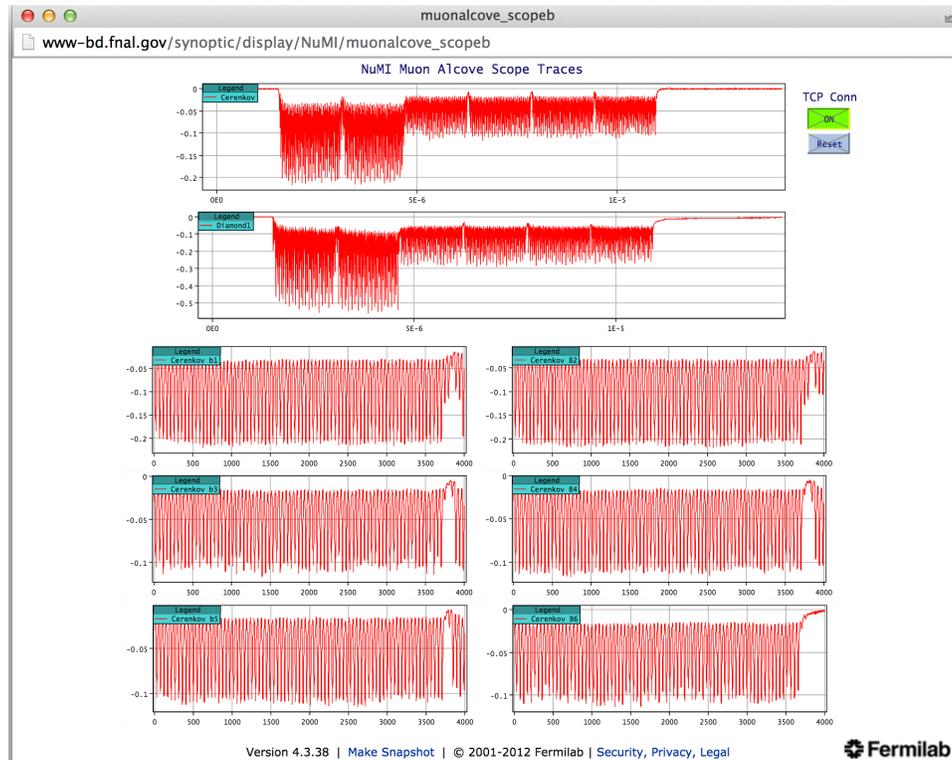

Figure 3.11: The realtime display of the muon detector prototypes in operation on the NuMI beam line. The top two panels are the Cherenkov counter and CERN diamond detector [5]. The signals are transmitted through low-loss heliax cable, and then the waveform is digitized at 2.5 GHz with a 12 bit dynamic range, and the recorded onto disk storage for analysis. The signal from the muons is contained in the short beam pulse "buckets" created by the accelerator RF structure. The fast timing allows the prompt muon signal to be easily separated from potential backgrounds such as stopped muon decays, beta decays, and neutrons.

fig:Muon

### 6 3.4.4 Installation

7 Installation will begin following the absorber installation and the installation of the stopped muon  
8 systems systems. The counters will be removed from the NuMI Alcove 1 area after calibration in  
9 the NuMI beam, and then stored until they are needed for DUNE. The gas handling system will  
10 be located nearby, also on the lower level of the Absorber Hall.

### 11 3.4.5 Operation

12 Because the system will be located in a radiation-controlled environment that will not be accessible  
13 during beam operation, it is essential that the electronics and gas handling system be both robust  
14 and remotely operable. The prototype system in use at the NuMI area can be relocated for that  
15 purpose, or if desired a new system may be constructed. Periodic access will be required to the  
16 utilities area to replace gas bottles.

17

## 18 3.5 Muon-Ionization Measurements

### 19 3.5.1 Introduction

20 Post-absorber muon measurements in most of the recent neutrino-beam experiments have typically  
21 employed a planar array of ionization counters to measure the muon profile and intensity. The  
22 NuMI beamline [3] and the K2K [6] [7] and T2K [8] [9] experiments have all utilized parallel-plate  
23 ionization detectors. These counters have been shown to work in the high-radiation environment.

24 K2K and T2K have also deployed solid-state silicon detectors [7] [10]. The advantage of silicon is  
25 that it is less sensitive to changes in the air temperature and pressure. However, these sensors are  
26 not as radiation-tolerant as the parallel-plate ionization chambers and will only be used in T2K  
27 for the initial beam operation.

28 DUNE is however in the process of evaluating CVD diamond detectors as ionization measurement  
29 devices. Their advantage is two-fold, they are much more radiation resistant than silicon, and  
30 they provide a much faster signal than ion chambers which allows them to distinguish between  
31 background and the prompt muon signal. They are also very stable and require no gas system.

32 The DUNE NDC plans to use the ionization devices, e.g. CVD diamond, to monitor the beam  
33 stability, direction and shape, and also potentially to determine the absolute flux of muons or to  
34 determine the muon-energy spectrum. Instead, the stopped-muon counters and gas Cherenkov  
1 detector will be used, respectively, to determine the flux and energy spectrum of the muons.

## 3.5.2 Reference Design

The reference conceptual design is to use CVD diamond ionization detectors arranged in two arrays. Each array will measure the centroid of the muon beam to insure a stable neutrino flux at the near and far detectors. The detectors are arranged in a diamond shaped arrays as shown in Figure 3.4 and Figure 3.12.

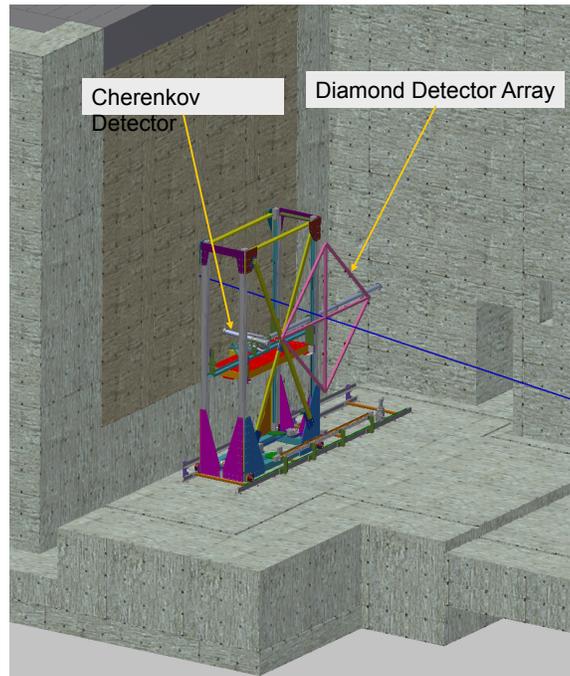

Figure 3.12: A model of the ionization detector layout behind the Cherenkov detector stand showing the 13 detectors in a grid configuration.

The reference design for DUNE includes two layers of ionization counters, one behind the absorber and a second one behind steel shielding blocks. DUNE wants to achieve a precision in the beam center of 0.2 milliradians (5 cm for a 250 m decay pipe). A quick study has determined the sensitivity for various arrangements of the ionization counters for each layer and Figure 3.14 shows the typical precision such a system can achieve. DUNE design was motivated by a desire to use a grid array with some of the counters removed, and still achieve the desired sensitivity, thus reducing the total number of needed counters.

Several different designs for the counter arrangement were studied and the area covered by the detectors was varied. A toy Monte Carlo model was developed to estimate the precision of each design. The muon profile was assumed to be a Gaussian with a spread of 130 cm in the  $x$  and  $y$  dimensions and a center at the origin. The standard deviation on the beam center was studied as a function of array coverage for several designs and for 2%, 5% and 10% random systematic error offsets. Figure 3.14 shows the precision of the detector array as a function of the width of the detector cross arrangement of the detectors.

The results show that the width of the detector array affects the precision more than the layout of the detectors. Increasing the array size improves the precision greatly.

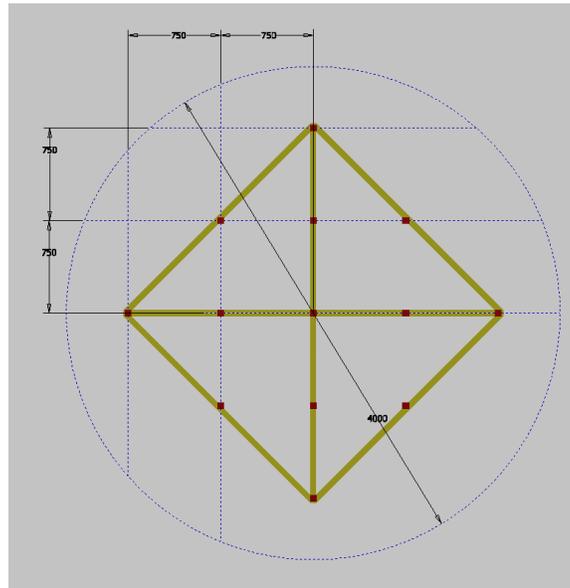

Figure 3.13: A model of one of the two ionization detector arrays that measure the muon flux and muon beam centroid.

fig:Diam

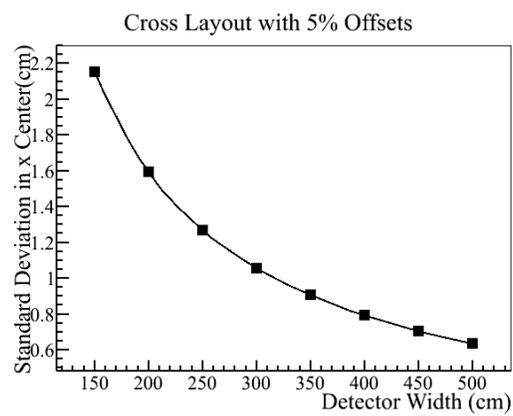

Figure 3.14: Precision as a function of detector width for a cross-shaped detector with assumed 5% random calibration offsets.

fig:cros

23 The DUNE muon ionization detector design consists of two arrays of ionization counters, which is  
24 motivated by the NuMI target experience. Over a period of several months, the number of events  
25 per proton on target gradually decreased over time, especially in the energy range from 2-4 GeV.  
26 This reduction in neutrino flux is attributed to target radiation damage. Figure ?? shows the ratio  
27 of the signal seen in the first muon alcove to the signal seen in the second muon alcove versus  
28 time. This ratio decreased in a similar manner over time. The first alcove was immediately after  
29 the absorber, while the second alcove was behind approximately 12 m of rock, and therefore saw  
30 only higher energy muons, since the lower energy ones would range out before reaching the second  
31 alcove. This gradual decrease in the ratio of the signals seen in these arrays was an indication of  
32 the target degradation and the relative reduction in the low-energy part of the neutrino and muon  
1 fluxes. <sup>1</sup>

2 It will be necessary to be able to monitor this ratio in DUNE on a spill-by-spill basis to look for  
3 signs of target degradation or horn failure. Therefore, a second ionization array, placed behind  
4 several layers of shielding blocks, will be necessary. In Figure 3.4 the second array is placed behind  
5 4 m of steel shielding. Since the density of steel is roughly 3 times larger than that of rock, this is  
6 comparable to the depth of the NuMI second muon alcove, which sits behind 12 m of rock. More  
7 detailed studies will need to be performed to determine if this is the optimal location for sensitivity  
8 to changes in the target density.

### 9 3.5.3 Prototype Design and Testing

10 The prototype testing of the diamond detectors is described above in the Cherenkov counter  
11 section, Section 3.4.3. For the DUNE ionization detectors, a small array of prototype counters will  
12 be built and operated in the existing NuMI alcove 1 to determine the optimal design and operating  
13 conditions for the DUNE monitors. This will be done in 2016 and 2017. It will provide a good  
14 field test in roughly the same environment as expected during DUNE operations. It will also be  
1 cross-checked against the existing NuMI muon-monitoring system. The goals of these tests are to  
2 understand the linearity of the response of these counters (by comparing the observed signal to  
3 variations in the beam intensity), their long-term stability and operational reliability.

### 4 3.5.4 Installation

5 The system installation will begin following completion of the Absorber Hall and LBNF 30 and  
6 the installation of the stopped-muon counter system (described in Section 3.6).

---

<sup>1</sup>Similar trends were seen in the ratios of the other muon alcove signals, but the first/second ratio saw the largest effect.

### 3.5.5 Operation

The muon-monitor-system data will be displayed in the control room at the Absorber Hall upper level on a spill-by-spill basis to monitor the beam stability and look for potential signs of target or horn degradation. This control room will be accessible during the beam operation. The data will also be displayed at central run control.

## 3.6 Stopped-Muon Detector

### 3.6.1 Introduction

The second system under development is stopped-muon counters, also called Michel-electron detectors. This method will measure the muon flux without suffering from some of the disadvantages intrinsic to systems that detect through-going muons. The strategy employed here is to stop muons in a material with significant carbon content and, via muon capture, to produce  $^{12}\text{B}$  that will in turn undergo  $\beta$  decay. The high-carbon material, in this case graphite, surrounds a Cherenkov radiator material which is sensitive to electrons from muon decay or high-energy beta decays. Figure 3.15 shows the conceptual design of a single stopped-muon counter.

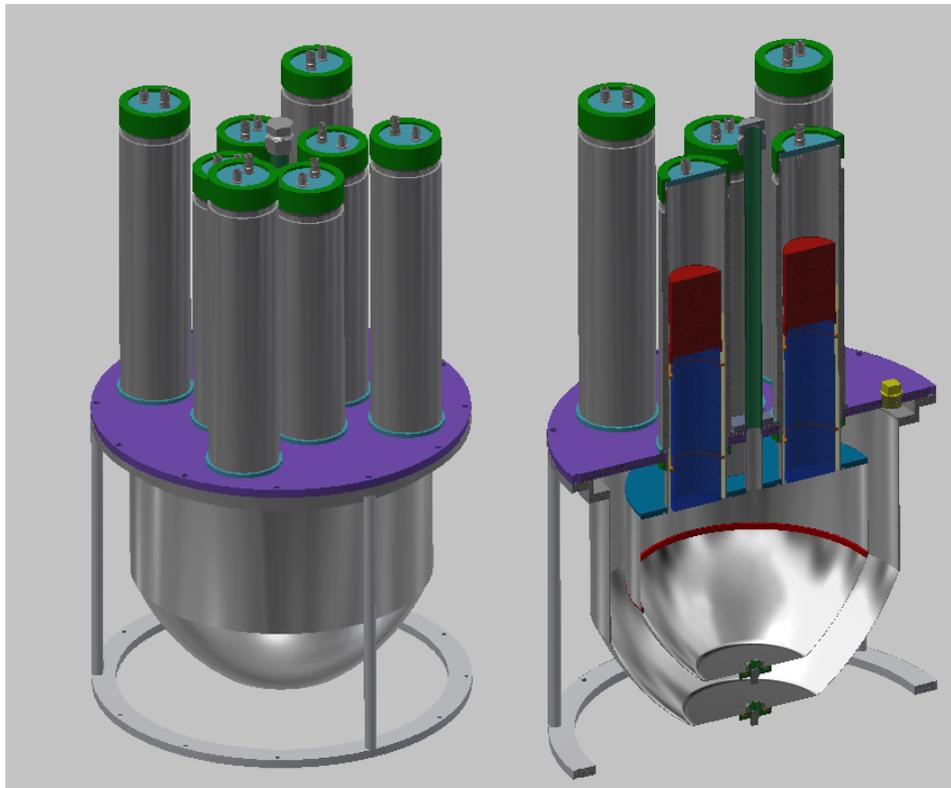

Figure 3.15: Conceptual design of a single Michel-electron detector (stopped-muon counter)

The detectors will only operate in the lower-rate environment that is present many microseconds

3 after the beam pulse is over. There are two possible modes for this type of system. The first is an  
4 integrating mode where the characteristic decay time of  $2.2 \mu\text{s}$  for muon decay and corresponding  
5 beta-decay lifetimes is used to unfold the total number of decays. The other mode under inves-  
6 tigation uses the ability to record individual decays rather than an analog current measurement.  
7 This mode may allow a more precise absolute normalization of the flux and fit the muon lifetime in  
8 the Michel-electron detector. This will provide a more robust cross-check on the muon signal than  
9 will ionization detectors, which are sensitive to delta rays, photon conversions and other charged  
10 particles.

11 Although this technique has never been tried on a large scale, a small demonstration project in  
12 K2K was able to see Michel decays with a  $10^3$  signal/background ratio and to measure the absolute  
13 rate with 30% precision [11].

### 14 3.6.2 Reference Design

15 The stopped-muon detector reference design is modular and based on a Cherenkov radiator of  
16 minimum size to contain a 52.8-MeV electron and distinguish it cleanly from lower-energy ra-  
17 dioactivity. This conceptual design employs a liquid mineral oil radiator. The radiator will be  
18 coupled to four photomultiplier tubes (PMT) or other photon counter. The entire module will be  
19 surrounded by a liquid scintillator veto layer, and the entire module then encased in a material  
1 that provides both a uniform-density stopping target for muons and some shielding from incoming  
2 neutrons. One or two signal channels will be associated with each module, and the full waveform  
3 from each channel over approximately 100 ms will be recorded on each beam pulse.

4 Nine modules will be placed just behind the absorber in a cross pattern. An additional 12 will be  
5 placed at multiple depths in the shielding in order to sample the muon flux from different energies,  
6 as shown in Figures 3.16. The shielding will simultaneously act to range out the muons and shield  
7 the detectors from neutrons. The Cherenkov light from Michel-decay electrons will exit the counter  
8 and be collected by either nearby PMTs or by a light guide which will guide the light to a remote  
9 optical sensor.

10 To probe the muon flux at lower energies, it may also be feasible and/or desirable to place some  
11 additional modules within the downstream part of the absorber or in the outermost radii of the  
12 decay-pipe shielding. The ability to do this may be limited, however, by the presence of muons  
13 from stopped, positively charged pion decays due to nearby hadron showers.

14 Besides the Michel decays of stopped muons, the system will independently measure both the  $\mu^+$   
15 and  $\mu^-$  stopped rates as a function of depth. While the  $2.2 \mu\text{s}$  decay time of the  $\mu^+$  is a reliable  
16 signature, in mineral oil roughly 8.5% of the  $\mu^-$  undergo capture on the  $^{12}\text{C}$  nucleus, and 15%  
17 of those leave behind a  $^{12}\text{B}$  ground state nucleus. That  $^{12}\text{B}$  nucleus will undergo  $\beta$  decay with a  
18 half-life of 20.20 ms and an electron spectrum with an endpoint of 13 MeV. This signal is expected  
19 to yield a reliable measurement of the rate of stopped  $\mu^-$ .

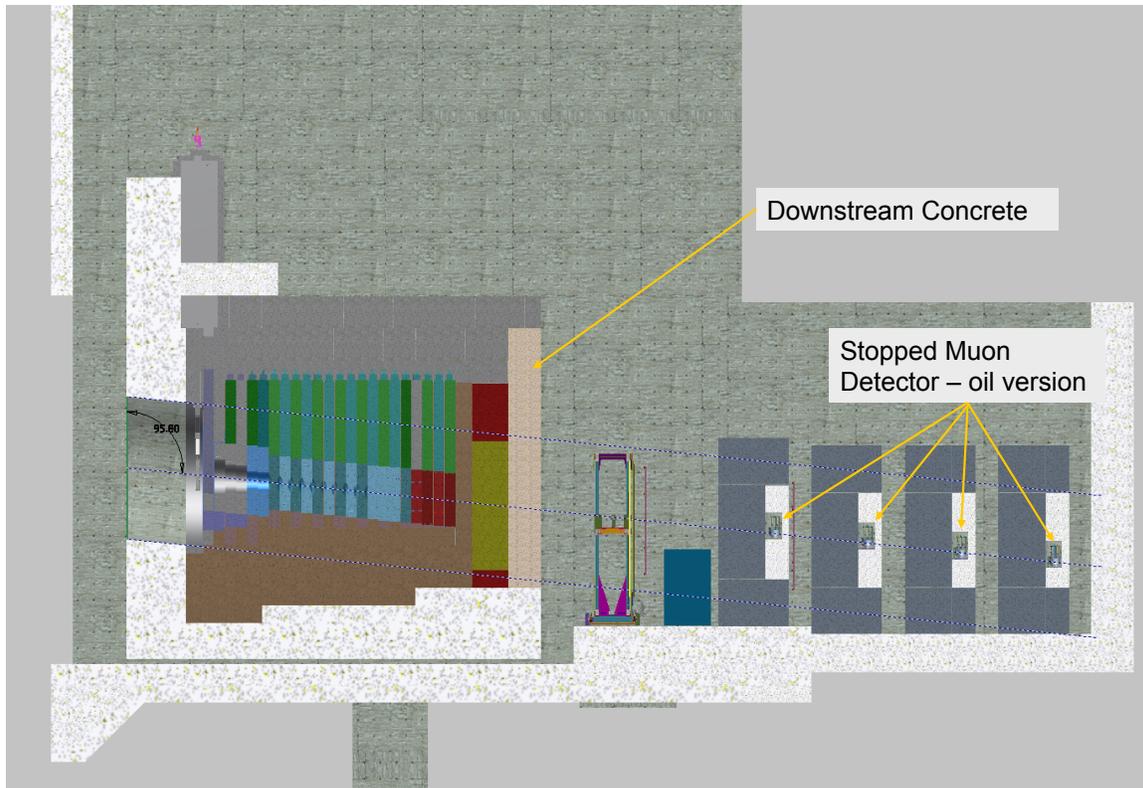

Figure 3.16: Stopped muon counter conceptual design. The figure shows the elevation view of the absorber at the end of the decay tunnel along with the locations of a subset of the stopped muon counters, and showing a possible arrangement of “blue blocks” and stopped muon detectors. In this case there is roughly 2 GeV of energy loss per wall of blue blocks. The final arrangement is under investigation and will depend on the final absorber design.

fig:Absc

### 20 3.6.3 Prototype Development and Testing

21 Prototype development activity for the Michel-electron detectors will be divided into studies of  
22 the rate and radiation environment where the detectors will be located and development of the  
23 counters themselves.

24 The radiation environment will be studied both with Monte Carlo simulations and by measure-  
25 ments from initial prototype detectors in the NuMI muon alcoves [3]. The prototypes will be  
26 installed into the alcoves in 2016 and 2017. Studies will be performed to determine if the photon  
27 sensors can survive the radiation environment at the location of the Michel detector. If the sen-  
28 sors can survive, they can be attached directly to the Cherenkov medium; if not, optical guides  
29 will have to bring the light to a lower-radiation area to the side of the beam. Potential radiation  
30 damage to the Cherenkov radiator itself will also be studied.

31 The detector design will focus on selecting radiator and shielding material, photon-detection tech-  
1 nology and control/readout hardware. Possible radiators include aerogel, which may be designed  
2 to be replaced periodically, and flowing liquids such as H<sub>2</sub>O or mineral oil. Long-timescale sat-  
3 uration from the very high-rate environment of the beam spill could affect the photon-counting  
4 devices [12]. Thus, it will likely be necessary to design fast-switching, high-voltage circuits that  
5 turn on the photon counters in the first few microseconds after the spill is over. A similar system  
6 was developed in the 1990s for the Brookhaven Muon (g-2) Experiment [13].

### 7 3.6.4 Installation

8 The stopped-muon counters will be installed after completion of the Absorber Hall and LBNF 30  
9 and installation of the absorber. They will be placed into the spaces between the blue-block walls  
10 on support frames. There will be access to the areas between the shield blocks from the side,  
11 and the stopped-muon counters will be designed so that they can be wheeled in from the side. If  
12 needed, they could then be moved around to measure the stopped-muon rates across the muon  
13 beam.

### 14 3.6.5 Operation

15 The muon-monitor-system data will be displayed in the control room on a spill-by-spill basis to  
16 monitor the beam stability. Because the system will be located in a radiation-controlled environ-  
17 ment that will not be accessible during the beam operation, it is essential that the electronics be  
18 designed for remote operation.

## Chapter 4

# Data Acquisition and Computing for the Near Detector System

## 4.1 NDS DAQ

The Near Detector System (NDS) Data Acquisition system (NDS-DAQ) collects raw data from each NDS detector's individual DAQ, issues triggers, adds precision timing data from a global positioning system (GPS), and builds events. The NDS-DAQ is made up of three parts, as shown in the block diagram of Figure 4.1, a master DAQ and one each for the near neutrino detector (NND, which is the FGT) and the BLM systems. The names for these are, respectively, NDS-MDAQ, NND-DAQ and BLM-DAQ.

### 4.1.1 NDS Master DAQ

The NDS Master DAQ (NDS-MDAQ) is designed to provide a high-level user interface for local run control and data taking, as well as for secure remote control and monitoring. It will serve as the primary interface to the NND-DAQ and BLM-DAQ and will include the following:

- slow-control system
- online data and DAQ performance monitoring
- raw data collection
- building of events
- data storage.

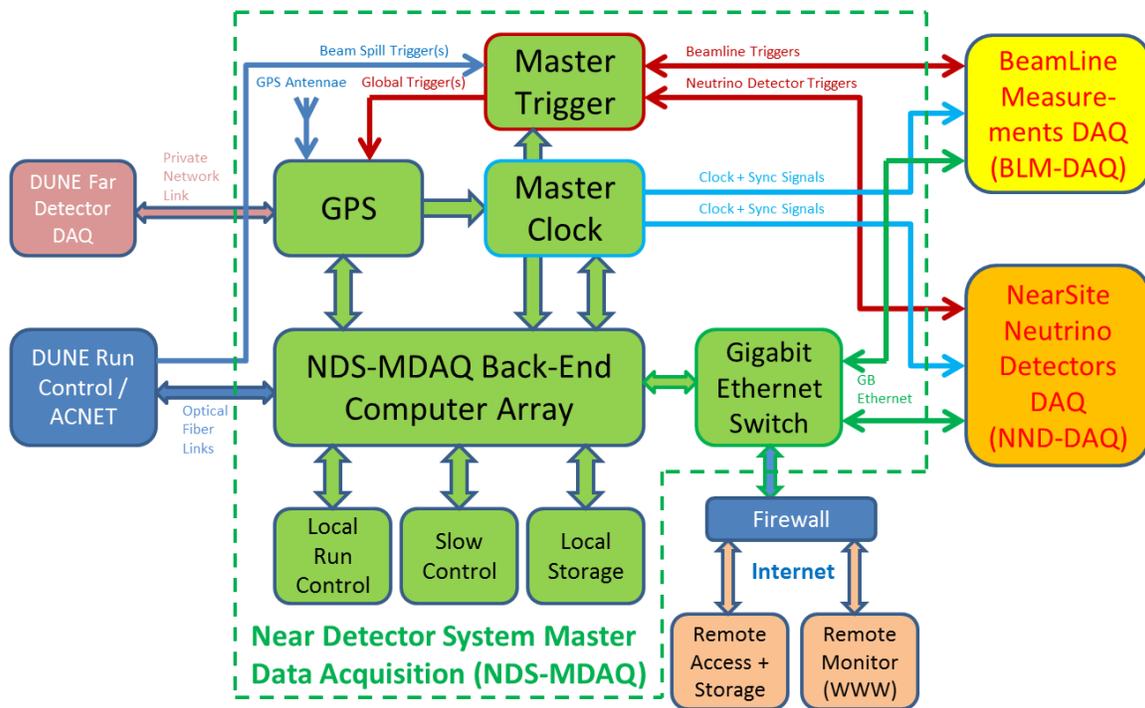

Figure 4.1: Near Detector System DAQ block diagram: The NDS-DAQ consists of the NDS Master DAQ (green blocks), the Beamline Measurement DAQ (yellow summary block) and the Near Neutrino Detectors DAQ (orange summary block). The NDS-DAQ connects to other portions of DUNE and LBNF, shown here in other colors (blue, light red, tan).

fig:DAQ\_

- 2 The NDS-MDAQ includes hardware two-way triggering for both the NND-DAQ and BLM-DAQ,
- 3 and GPS hardware for precision time-stamping and global clock synchronization. The design is
- 4 currently based on a channel count estimate of approximately 433,000 from the near neutrino
- 5 detector, plus < 1,000 from the beamline detectors. Custom electronic components for the NDS-
- 6 DAQ are based on existing custom designs from other experiments, e.g., T2K and ATLAS, and
- 7 implement commercial components for the trigger modules, clock and timing synchronization, GPS
- 8 and environmental monitoring.

### 9 4.1.2 Near Neutrino Detector DAQ (NND-DAQ)

: nnd:daq

- 10 The Near Neutrino Detector Data Acquisition system (NND-DAQ) collects raw data from the DAQ
- 11 in each NND subdetector and connects to the NDS Master DAQ via Gigabit Ethernet. A block
- 12 diagram of the NND-DAQ is shown in Figure 4.2. The NND-DAQ will mainly consist of a scalable
- 13 back-end computer array, interconnected to the individual subdetector DAQs via Gigabit Ethernet,
- 14 and specialized electronics modules for trigger processing and clock synchronization. It interfaces
- 15 to the NDS-MDAQ for run control and data collection. The NND-DAQ will also have its own
- 16 local run-control setup, consisting of a number of desktop workstations to allow independent local
- 17 runs that include NND subdetectors only; this is useful during detector commissioning, calibration
- 18 runs, stand-alone cosmic runs, or other runs where the beam is stopped or not needed.

19 The quantity of computers required for the NND-DAQ back-end system is highly dependent on the  
 20 number of channels and expected data rates of the individual neutrino detectors. One back-end  
 21 computer should be able to handle approximately 3,000 channels for sustainable and continuous  
 22 runs. Assuming a total of 433,000 channels for all NND subdetectors combined, about 150 back-end  
 23 computers would be needed.

24 Trigger signals from each subdetector will be collected and pre-processed by a trigger electronics  
 25 module, similar in design to the NDS trigger or master-clock modules of the NDS-MDAQ design.  
 26 Depending on the run mode, this module could feed local trigger decisions to the detector DAQs  
 27 for data collection, or it could forward NDS triggers from the NDS-MDAQ or higher levels to the  
 28 NND subdetector DAQs. A slave-clock electronics module, similar to the master-clock module in  
 29 the NDS-MDAQ, distributes clock- and time-synchronization signals from the NDS-MDAQ to all  
 30 NND subdetectors.

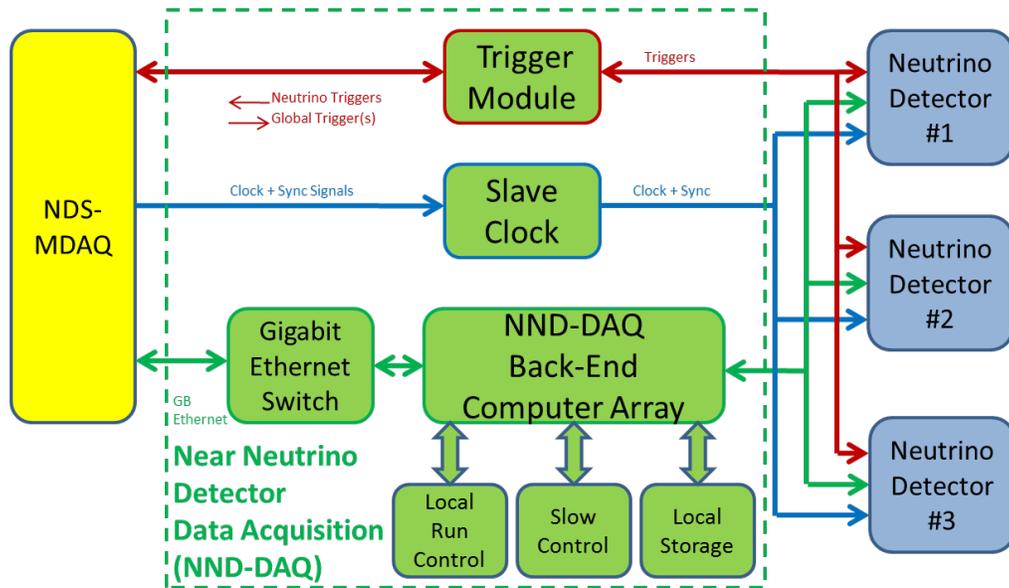

Figure 4.2: A block diagram of the Near Neutrino Detector DAQ (NND-DAQ).

fig:DAQ\_

### 31 4.1.3 Beamline Measurements DAQ (BLM-DAQ)

32 The BLM-DAQ will mainly consist of a scalable back-end computer array, inter-connected to the  
 1 individual beamline measurement detector DAQs via Gigabit Ethernet and specialized electronics  
 2 modules for trigger processing and clock synchronization. It interfaces to the NDS-MDAQ for run

3 control and data collection. It will also have its own local run-control setup, consisting of a num-  
4 ber of desktop workstations to allow independent local runs that include beamline measurement  
5 detectors only; this is useful during detector commissioning, calibration runs, stand-alone cosmic  
6 runs or other runs where the beam is stopped or not needed.

## 7 **4.2 NDS Computing**

8 The computing system encompasses two major activities: online computing with required slow-  
9 control systems, and offline computing for data analysis and event simulation. The computing  
10 components are based on currently available commercial computing and gigabit networking tech-  
11 nology, which is likely to improve over the next years without driving costs up for the final design.

computing

# Chapter 5

## Measurements at External Facilities

### 5.1 Introduction

The technical components that would be needed to implement the strategies described in this chapter are outside the scope of the DUNE NDS conceptual design. This information is included in this document because it complements the conceptual design and expands the NDS capabilities to more closely meet the mission need without increasing the project cost.

### 5.2 External Neutrino-Beam Measurements

As discussed in Section 5.3.2, DUNE's strategy for neutrino-beam measurements includes making measurements of the Far Detector response to a known flux of neutrinos, and NuMI is the only appropriate beam line to use for the neutrino source.

To implement this strategy, appropriate detectors will need to be built. A plausible scenario would be a liquid argon TPC detector of 20-30 tons in the current location of the Minerva experiment, in front of the MINOS near detector. In that way, the MINOS near detector could be used to measure the charge of muons exiting the TPC. The TPC would be designed using the same readout technology that is used in the DUNE Far Detector. Once an optimal detector arrangement is determined, DUNE would use the same beam simulation and same muon measurements to apply that knowledge to the LBNF beam and Far Detector.

### 5.3 External Hadron-Production Measurements

Uncertainties on hadron production will translate into uncertainties in the neutrino fluxes in the DUNE Far Detector, since the neutrinos are produced by hadrons decaying in the decay pipe.

Precise calculations of neutrino fluxes in high-energy accelerator beams are limited at present by our knowledge of hadron production cross-sections in hadron-nucleus collisions. The modeling of strong-interaction cascades and hadronic yields from “thick” targets (up to a couple of interaction lengths) relies on detailed knowledge of underlying physics and cross-sections, which must be provided as a starting point to simulations. The resulting prediction of the flux of neutrinos, produced from decays of pions, kaons, and muons emerging from a hadronic shower and beam line re-interactions, is an essential part of simulations of most neutrino experiments.

Two-detector neutrino oscillation experiments predict the neutrino flux at the far detector by using neutrino fluxes “calibrated” (or appropriately scaled) by event energy spectra measured in the near detector. However, even these experiments must rely on the beam simulations since the decay pipe (where most beam neutrinos are created) provides different angular acceptance for the two detectors. In addition, experiments using near and far detectors based on different detection technologies further complicate the extrapolation. This chapter outlines the DUNE strategy for augmenting the capabilities of the BLM with external measurements of secondary-beam particles.

### 5.3.1 Background

A complete knowledge of the momenta and decay points of the kaons, pions and muons would be sufficient to completely predict the un-oscillated flux of neutrinos at the Near and Far Detector locations. This would require knowledge of:

- the phase-space distribution of the initial proton beam
- details of all materials present in the target, horn and decay pipe areas
- the electromagnetic focusing characteristics of the magnetic horn
- the detailed development of the hadron cascade, spawned by the initial proton, that passes through the target/horn/decay pipe
- the meson-to-neutrino decay rates

With careful engineering design and careful control of the materials in the target area, all of these items can be simulated accurately except hadronic cascades in the target, horn and decay pipe. The simulation of the hadronic cascade requires accurate knowledge of the hadron scattering cross sections, for which there are no first-principle calculations. These cross sections must therefore rely on models, which in turn require hadron-production measurements that span particle type, particle energy and the various materials found in the target, horn and decay pipe.

At the present time, a sufficient body of hadron-production measurements does not exist to achieve DUNE’s desired accuracy of 4-5%, as determined by the irreducible error on the statistical uncertainty for the appearance-measurement back-ground, although this is expected to improve over time. As the BLM system described in Chapter 3 cannot meet this requirement alone, a near-far comparison will be more complicated than in certain other neutrino-oscillation experiments, e.g.,

13 MINOS experiment [\[2\]](#). muon-validation

### 14 5.3.2 Strategy as-strat

15 The current approach is to rely on measurements made externally (outside the scope of DUNE) to  
16 calibrate detector response and flux simulations, and to relate these measurements to DUNE. This  
17 would be done through the use of a common simulation code and through measurements of tertiary  
18 muons in both DUNE and the external facility, using nearly identical tertiary muon-measurement  
19 systems.

20 In order to keep the uncertainty in the near/far event-rate ratio from being limited by systematic  
21 uncertainties in the flux, the DUNE flux simulation must be accurate at the 4-5% level. Efforts at  
22 this stage are intended to understand the effect of the uncertainties in hadron-production in the  
23 beamline on overall DUNE sensitivities, to determine what further measurements may be needed  
24 by DUNE and to estimate their potential cost to the Project.

25 The measurements that DUNE would require from an external facility begin with the primary  
26 hadron-production cross sections in the proton-target material, followed by similar studies in thick  
27 targets, and finally hadron yields after passage through the complete target and focusing-horn  
28 system. In addition, hadron-interaction cross sections on materials in the decay pipe and absorber  
29 can be important in flux calculations.

30 External hadron-production measurements are expected to play a critical role once the Far Detector  
31 has accumulated sufficient statistics toward the end of the running period to make systematic errors  
32 on the flux a dominant source of error in the oscillation measurement.

### 33 5.3.3 Use of External Facilities for Measurements

34 Historically, a number of hadron-production experiments have contributed directly to the outcome  
35 of neutrino experiments by measuring meson production from the proton targets used by those  
36 experiments, and hence providing a constraint on their neutrino fluxes. For example, the HARP  
37 data ref: HARP [14] contributed directly to MiniBooNE and the SPY ref: SPY [15] experiment contributed directly to  
38 NOMAD. Since their contributions were crucial to those neutrino experiments, it is also expected  
39 that DUNE will require some dedicated hadron-production measurements. In the future, the MIPP  
40 experiment at Fermilab is planning to contribute its measurements to the NO $\nu$ A experiment, and  
41 the NA61 experiment Abgrall: 2011Pae, Abgrall: 2011ts [16, 17] is contributing to the T2K experiment Abe: 2012av [18].

42 A suitable apparatus for DUNE's hadron-production measurements is the collection of equipment  
43 and detectors used by the MIPP experiment at Fermilab Ishenower: 2006zp [19]. A full suite of DUNE-related hadron-  
44 production measurements would require the installation of the DUNE horn-focusing elements and  
45 associated power supplies in front of a future incarnation of MIPP in the meson area at Fermilab.  
46 This kind of effort could be within the scope of the DUNE Project and could be postponed until  
47 after DUNE construction or even after DUNE operations have stopped.

## 5.4 The US-NA61/SHINE Program

13

L-usna61

14 A proposal to make measurements for the Fermilab neutron program with the NA61/SHINE  
 15 experiment has been funded by DOE/HEP [20, 21], US-NA61, and recommended by the CERN  
 16 SPSC. NA61/SHINE is situated in the North Area of CERN on the H2 beam line.

17 The detector, schematically shown in Figure 5.1 is comprised of two large air gap, Helmholtz-coil  
 18 superconducting magnets with a total bending power of 9 T-m. The detector is instrumented  
 19 with gas TPC tracking, time-of-flight counters, and a hadron calorimeter (at very forward angles).  
 20 The US-NA61 measurements will provide hadron-production data sufficient for predicting neutrino  
 21 fluxes at DUNE. A pilot run of 120 GeV/c protons interacting on a thin 4% graphite target was  
 22 taken by NA61 during July, 2012. A 4-week dedicated physics run is scheduled for October, 2015.

23 The run plan for the 2015 data is shown in the table in Figure 5.2. The initial run will focus on  
 24 proton and pion data at 120 GeV/c and 60 GeV/c energies. This will constrain well extrapolations  
 25 from higher and lower energies that are currently under use in neutrino beam simulations.

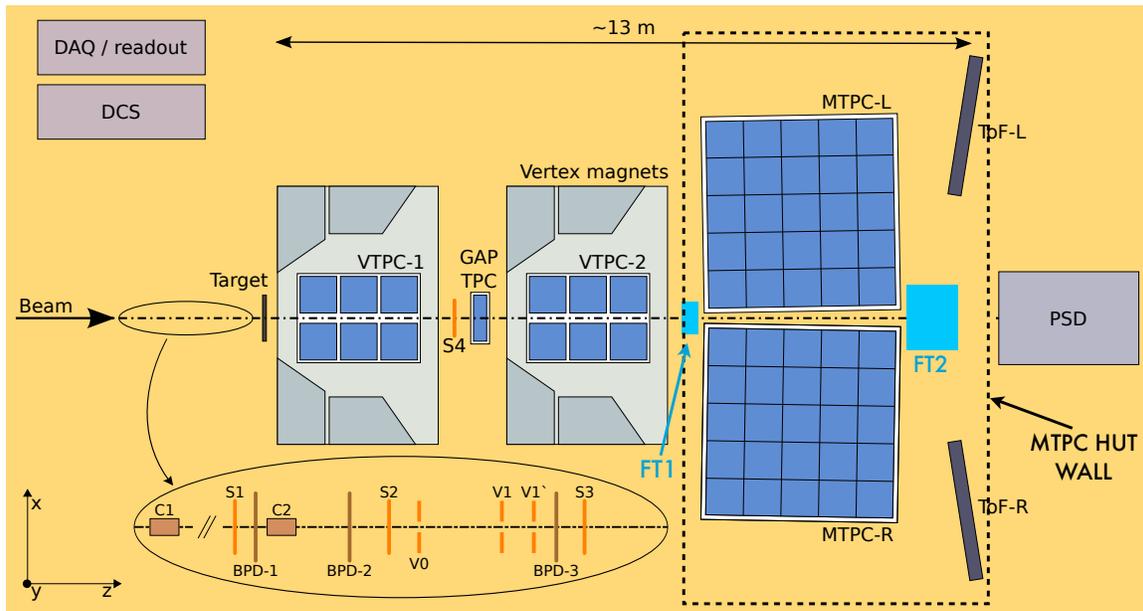

Figure 5.1: A schematic drawing of the CERN NA61 detector, a hadron production and heavy ion experiment designed to measure hadrons over a large part of the relevant phase for neutrino experiments. The TPCs, shown in blue, can separate pions from protons and kaons.
